Abstract

We utilized the Integrated Multi-Satellite Retrievals for Global Precipitation Mission version 6 (IMERG) rainfall observation (available in real time) over India to determine the onset and ~~withdrawal~~ of the rainy season. The annual mean climatology derived from IMERG observations over India aligned closely with the rain gauge-based India Meteorological Department observation. The IMERG rainfall time series was randomly perturbed to generate 101 ensemble members at every grid point of the rainfall analysis to obtain a corresponding ensemble of the onset and ~~withdrawal~~ dates of the rainy season. The perturbations were designed to sample the uncertainty due to random synoptic or mesoscale rain events influencing the diagnosis of the onset/~~withdrawal~~ dates at the granularity of the IMERG observations (~~available~~ at 10 km grid). Following earlier studies, we find from the IMERG dataset that seasons with an earlier onset date are strongly related to a lengthier and wetter season, whereas seasons with a later onset date correspond to a shorter and ~~a~~ drier season. In contrast, the connections between ENSO and IOD ~~with~~ the onset, ~~withdrawal~~, seasonal length, and rainfall ~~of the rainy season~~ were comparatively weaker over most of India. The generation of ensembles in this study underscores the potential for real-time application of generating reliable, probabilistic seasonal outlooks of the rainy season over India by leveraging the local links amongst onset date, seasonal length, and seasonal rainfall anomalies. This potential is further confirmed by the high probabilistic skill scores of the seasonal outlooks using the area under the relative operating characteristic curve method.

1. Introduction

India's water and agriculture sectors rely heavily on copious summer monsoon rainfall, emphasizing its critical role in defining the country's agrarian economy and water resource management (Gadgil and Gadgil 2006). The seasonal progression of the Indian Summer Monsoon (ISM) season has an impact not only on agricultural yields but also on other sectors such as economy and ecology (Lal 2000). Based on rainfall patterns, wind conditions, and outgoing longwave radiation, the India Meteorological Department (IMD) officially declare the date of monsoon onset over Kerala (MoK) each year. In a normal year, the ISM season begins in southern peninsular India on June 1st (with MoK), spreads throughout the country by mid-July, and then begins to retreat on September 1st (Pai et al. 2020).

There are many different definitions for the monsoon onset; however, it is typically considered as a quick, substantial, and prolonged increase in rainfall after May 10th, accompanied by a persistent change in wind direction to southwesterlies associated with the summer monsoon flow (Pai and Rajeevan 2009). In addition to the rainfall-based definitions (e.g., Ananthakrishnan and Soman 1988; Noska and Misra 2016; Misra et al. 2017b), several other atmospheric dynamical and thermodynamical variables (winds, outgoing longwave radiation, temperature, moisture flux convergence, and precipitable water) were utilized to identify the onset of summer monsoon rainfall (e.g., Fasullo and Webster 2003, Zeng and Lu 2004, Prasad and Hayashi 2005, Joseph et al. 2006, Wang et al. 2009, Walker and Bordoni 2016, Stolbova et al. 2016). These variables provide a comprehensive understanding of the atmospheric conditions and dynamics that influence the onset and total summer monsoon rainfall over India. According to Bombardi et al. (2019), monsoon onset detection methods can be grouped into local-scale and regional-to-large-scale approaches, though the latter often show weak correlation with local observations. All these approaches produce somewhat similar onset dates, but their connections with the local-scale onset of the rainfall during the ISM differ (Moron and Robertson 2014; Noska and Misra 2016; Fitzpatrick et al. 2016).

Owing to variations in the onset and withdrawal date of the monsoon season there are considerable spatial and temporal variations in the availability of the rainwater and length of the rainy season

80 (determined solely based on rain rates) over India (Joseph et al. 1994; Lal 2000; Wang et al. 2002;
 81 Misra et al. 2017a; Misra et al. 2018). Preenu et al. (2017) indicate from IMD archive that the
 82 earliest onset of the ISM was May 11, 1918, and the most delayed onset of ISM was Jun 18, 1972.
 83 Several studies discuss the interannual variability of monsoon onset dates in India and its
 84 teleconnection with El Niño and the Southern Oscillation (ENSO) and the Indian Ocean Dipole
 85 (IOD, Xavier et al. 2007; Sankar et al. 2010; Misra et al. 2017a; Pradhan et al. 2017; Choudhury
 86 et al. 2021). In ENSO and IOD years, the monsoon onset is altered by the modulation of the
 87 teleconnections with SST anomalies in the tropical oceans, which affect the Walker and Hadley
 88 circulations, respectively (Pradhan et al. 2017). Significant changes in the large-scale atmospheric
 89 patterns over the monsoon areas are identified during the onset of the monsoon over India (Joseph
 90 et al. 1994). According to Wang et al. (2013), the interannual variations in ocean-atmosphere
 91 interaction processes significantly influence the association between the monsoon onset and
 92 ENSO, which is driven by the meridional SST gradient across the Indian Ocean. Noska and Misra
 93 (2016) show that the variations in the onset and withdrawal date of the rainy season over India that
 94 largely overlaps with ISM are linked to the variability of the cross-equatorial upper-ocean heat
 95 transport in the Indian Ocean, variations in large-scale atmospheric and oceanic circulations, and
 96 regional ocean-atmosphere thermal gradients. In addition, internal variability of ISM arising from
 97 intraseasonal oscillations (ISOs), can significantly influence the monsoon rainfall and as well as
 98 the onset and withdrawal characteristics of the ISM (Goswami and Ajaya Mohan, 2001; Goswami
 99 and Xavier, 2005; Karmakar and Misra 2019). Monsoon ISOs are typically classified into active
 100 (above normal) and break (below normal) phases, and the frequency of these phases plays a crucial
 101 role in determining the seasonal mean monsoon rainfall (Goswami and Ajaya Mohan, 2001).
 102 Karmakar and Misra (2019) found that a majority of local onset dates (59%) occur during the
 103 positive developing phases of high-frequency ISOs, while a majority of withdrawal dates (62%)
 104 occur during the positive decaying phases of low-frequency ISOs.

106 It may be noted that we make a subtle distinction between the ISM and rainy seasons, with the
 107 latter solely determined by rain rates which includes pre- and post-monsoon seasonal rainfall (e.
 108 g., Noska and Misra 2016) while the former is usually a fixed calendar season (June to September)
 109 and coincides additionally with the seasonal cycle of circulation features and other thermodynamic
 110 factors. Figure S1 highlights the difference between the rainy season and climatological ISM (June

Deleted: influenced by

Deleted: variable

Deleted: fixed southwest monsoon season

118 to September), which makes it evident that the rainy season accumulates more rainfall in southern
 119 peninsular India and in regions east of the central monsoon region. Similarly, when compared to
 120 the JSM season, the rainy season has slightly less total rainfall over both western, northern India,
 121 and parts of northeastern India. It may be noted that the definition of the rainy season allows for a
 122 variable length compared to the fixed calendar season of, which stems from the former including
 123 pre-monsoon rainfall and rainfall from pre-monsoon and post-monsoon rainfall. For instance,
 124 tropical cyclones are also included in the rainy season defined here, and they significantly
 125 contribute to the annual rainfall in some parts of eastern India. Pre- and post-monsoon tropical
 126 cyclones can contribute up to 25% of the yearly rainfall in some parts of India, even though the
 127 southwest monsoon is the main component of our defined rainy season (Khouakhi et al. 2017).

129 The information about the arrival of the monsoon rainfall is imperative for farmers to plan their
 130 strategy for the upcoming season. There are many attempts to predict the MoK; however, it
 131 remains a challenge due to the intricate interplay between large-scale atmospheric circulation and
 132 localized convective processes, resulting in substantial spatial variability in onset dates (Kung and
 133 Shariff 1980; Rajeevan and Dubey 1995; Pai and Rajeevan 2007; Pradhan et al. 2017). Many
 134 studies have shown that variations of the MoK have very little influence on the mean rainfall
 135 anomalies of the ISM (Dhar et al. 1980; Mooley and Parthasarthy 1984; Mooley and Shukla 1987;
 136 Misra and DiNapoli 2014). Furthermore, MoK is known to have insignificant relationship with
 137 subsequent progression of the onset isochrones of the ISM (Bansod et al. 1991; Fasullo and
 138 Webster 2003; Pai and Rajeevan 2007). Noska and Misra (2016) proposed an objective method to
 139 define the onset and withdrawal of the rainy season based on area averaged all India daily rainfall,
 140 and they found that mean anomalies of the rainy season are closely linked with variations in the
 141 onset and withdrawal dates of the rainy season. In addition, they validated the defined onset and
 142 withdrawal of the rainy season for consistency by comparing them with the seasonal evolution of
 143 key dynamic and thermodynamic variables associated with the ISM. In a following study, Misra
 144 et al. (2018) obtained local onset (withdrawal) dates of the Indian rainy season at the granularity
 145 of the rainfall analysis and showed that they are negatively (positively) correlated with rainfall
 146 anomalies of the rainy season across the Indian region. These studies suggest that monitoring the
 147 local onset date of the rainy season provides a good indication of the evolution of the seasonal
 148 length and rainfall of the forthcoming rainy season, (i.e., the entire duration of the rainy season at

165 each grid points) and supporting its use in predictability studies. Bhardwaj and Misra (2019) found
166 that Remotely Sensed Rainfall Products such as Tropical Rainfall Measuring Mission (TRMM)
167 Multi-satellite Precipitation Analysis (TMPA) produce local onset and withdrawal dates similar to
168 IMD observations. In comparison to traditionally identified onset of ISM, which are often limited
169 to defining the onset over Kerala (e.g., MoK), the proposed method enables the generation of
170 spatially continuous maps of onset date evolution. By capturing regional heterogeneity, it provides
171 a more nuanced understanding of the spatiotemporal progression of onset of the rainy season
172 across India. This simple rainfall-based definition was found useful for monitoring the onset of the
173 rainy season in real-time and issuing the outlook of the rainy season over various regions such as
174 Florida (Misra et al. 2022), and Central America (Rodgers et al. 2024).

Deleted: seasonal

176 Many studies have used the IMERG data set as one of their primary dataset for the analysis of the
177 ISM (Bushair et al. 2019; Thakur et al. 2020; Saikrishna et al. 2021; Phadtare et al. 2023). In this
178 study, we employ a rainfall-based objective method to define the local onset and withdrawal of the
179 rainy season, leveraging the high-resolution IMERG dataset available since January 2001. Our
180 approach captures the actual arrival and retreat of persistent rainfall at each grid point by
181 identifying the onset and withdrawal of the rainy season. This approach also accounts for pre- and
182 post-monsoon rainfall, providing a more complete representation of the rainy season—particularly
183 in regions where events such as tropical cyclones contribute significantly to seasonal rainfall totals.
184 In this study, utilizing IMERG's 12-hour latency product, we demonstrate the potential for real-
185 time monitoring of the onset of the rainy season, which aids in anticipating the anomalies of the
186 seasonal length and seasonal accumulated rainfall (hereafter referred to as seasonal rainfall) across
187 India. Motivated from the grid-point level definition of onset and withdrawal dates established by
188 Misra et al. (2018) and Bhardwaj and Misra (2019), this study advances this framework by how
189 the IMERG 12-hour latency product can be effectively used to monitor these parameters at fine
190 spatial scales, enabling better anticipation of anomalies of the seasonal length and seasonal rainfall.
191 In addition, the novelty of this work lies in the use of a perturbation technique applied in the
192 diagnosis of onset/withdrawal dates of the rainy season over India following Misra et al. (2023)
193 and Rodgers et al. (2024) to generate 101 ensembles of daily rainfall data. This approach is the
194 first of its kind over the Indian region and allows us to define an ensemble of local onset and
195 withdrawal dates, aiding in the probabilistic estimate of the evolution of the rainy season that

Deleted: demise

Deleted: demise

Deleted: providing a

205 accounts for observational and analysis uncertainties. Hereafter, the term ‘onset’ refers to local or
206 grid point-specific onset dates of the rainy season.

207
208 Additionally, this study explores the interannual variation of the evolution of the rainy season and
209 its link to large-scale forcing such as ENSO and IOD and compares their viability as predictors of
210 the rainy seasons to the local links we establish with the variations of the onset dates. We believe
211 that the insights from this study will have significant potential applications in agricultural planning
212 and water resource management.

214 2. Data and Methodology

215 2.1 Data

216 The analysis performed in this study utilized daily precipitation data from the IMERG version 6
217 (Huffman et al. 2019). This dataset is part of the Global Precipitation Measurement (GPM)
218 mission, which was launched in 2014 and is co-operated by NASA and the Japan Aerospace
219 Exploration Agency (JAXA). The 0.1° grid resolution (~10 km) IMERG data are available at half-
220 hourly intervals from June 2000 to the present. The dataset comprises early, late, and final run
221 products, which have latencies of approximately 4 hours (Early), 12 hours (Late), and 3.5 months
222 (Final). The IMERG late run incorporates data from multiple sources, such as satellite microwave
223 and infrared estimations, precipitation gauge analysis, and other potential precipitation estimators.
224 This dataset provides detailed temporal and spatial coverage for both the TRMM and GPM eras
225 worldwide. However, in this study, we used the daily 12-hour latency product (daily averages were
226 estimated from half-hourly products), which has great potential for monitoring the rainy season in
227 real-time. To assess the fidelity of the 12-hour latency product of IMERG over India, we have
228 compared it with the corresponding Final product of IMERG and also used rain gauge-based IMD
229 gridded rainfall data for the period 2001 - 2023 at 0.25° × 0.25° resolution (Pai et al. 2014) as a
230 validation dataset. Additionally, we defined the onset and withdrawal dates of the rainy season
231 using the daily NOAA Climate Prediction Center (CPC) precipitation data set (Xie et al. 2007)
232 and compared them with IMERG.

234 2.2 Methodology

235 2.2.1 Onset and Retreat

Deleted: IMERG

Deleted: we have

Deleted: demise

Deleted: and compared them with

Deleted: IMERG

Deleted: 2007).

242 This study uses a simple objective definition to identify the onset and cessation dates of the wet
 243 season over India which are determined by finding the minima and maxima of the cumulative
 244 rainfall anomaly curve (Liebmann and Marengo 2001). The cumulative anomaly of the daily
 245 rainfall at a day j (i.e., $C_i(j)$) for a year i at each grid point is estimated as:

$$C_i(j) = \sum_{j=1}^j (R_i(j) - R) \quad (1)$$

249 where $R_i(j)$ is the rainfall for day j of year i , R is the climatology of the annual mean rainfall for a
 250 given grid point. The $C_i(j)$ for 365/366 days in a year represents the cumulative rainfall anomaly
 251 curve. After the onset and withdrawal dates of the season are determined, we count the number of
 252 days between them to define the seasonal length. Seasonal rainfall of the rainy season refers to the
 253 daily rainfall that accumulates from the day of onset date to the withdrawal date.

255 2.2.2 Perturbation

256 The motivation to perturb the timeseries is to account for the uncertainty of random synoptic or
 257 mesoscale events that is potentially unrelated to the seasonal cycle, which could affect the
 258 diagnosis of the onset/withdrawal date of the rainy season. The threat of false diagnosis of
 259 onset/withdrawal dates of the rainy season is acute from the proposed methodology since this
 260 diagnosis is computed at the granularity of the rainfall analysis. Therefore, generating an ensemble
 261 of onset/withdrawal dates of the rainy season that accounts for this uncertainty is essential. The
 262 perturbations are generated randomly by replacing the rainfall of each day in the original timeseries
 263 for a given grid point by rainfall in the range of ± 3 days. The range of ± 3 days used in the
 264 generation of the perturbed timeseries covers the uncertainty in the occurrence of the synoptic (1
 265 to 7 days) to meso-scale (1 to 3 days) rain features of the rainy season. In this manner, an ensemble
 266 of 101 (100 perturbations + 1 original) timeseries are generated. The diagnosis of the
 267 onset/withdrawal date of the rainy season will converge or diverge amongst the ensemble members
 268 if it is found to be insensitive or sensitive to these random rain events, respectively.

270 2.2.3 Signal-to-noise Ratio

271 We estimated the signal-to-noise ratio of the four quantities by utilizing the 101 ensemble
 272 members.

$$S_{noise}^2 = \frac{1}{A(B-1)} \sum_{a=1}^A \sum_{b=1}^B (X_{ab} - \bar{X}_b)^2 \quad (2)$$

$$S_{signal}^2 = S_{em}^2 - \frac{1}{b} S_{noise}^2 \quad (3)$$

Where, X belongs to any of the four quantities such as onset date, withdrawal date, seasonal length, and seasonal rainfall anomalies of the varying rainy season, a and b are indices for A years and B ensemble members, respectively. S_{em}^2 represents the measured total signal variance in the data over A years and which is defined as:

$$S_{em}^2 = \frac{1}{(A-1)} \sum_{a=1}^A (X_a - \bar{X})^2,$$

And $\bar{X}_a = \frac{1}{(B-1)} \sum_{b=1}^B X_{ab}$, $\bar{X} = \frac{1}{(A-1)} \sum_{a=1}^A \bar{X}_a$,

The signal-to-noise ratio is then given by:

$$ratio = \frac{S_{signal}^2}{S_{noise}^2} \quad (4)$$

When $ratio < 1$ then it indicates that noise (or chaotic variations) is dominant, and the signal dominates when $ratio > 1$. A strong signal indicates that perturbing the rainfall time series will not substantially influence the diagnostics of the onset date, withdrawal date, seasonal length, and seasonal rainfall anomalies.

2.2.4 Significance test

In this study, we first estimate the two-tailed p-values of the correlation coefficients using the t-statistic. Further, following Benjamini and Hochberg (1995), we conduct a test for false rejection on all temporal correlations to assess its robustness, which is necessary because of the large number of simultaneous statistical significance tests conducted across all grid points of the domain. This process involves adjusting the p-value (Benjamini and Hochberg 1995) to control the false rejection of the null hypothesis, also known as the false discovery rate. By controlling the false discovery rate, we enhance the confidence in the significance of the findings.

320 The seasonal mean rainfall over India observed from IMERG is found to be comparable with IMD
321 observation and superior to other satellite products over the region (Saikrishna et al., 2021). This
322 is further confirmed in Figs. 1a-c which compares the 23-year annual mean rainfall climatology
323 between IMERG observations and the corresponding IMD rainfall dataset. It may be noted that in
324 Equation (1), the annual mean rainfall climatology (R) at each grid point is used to determine
325 onset dates and withdrawal dates of the rainy season over India (e.g., Misra et al., 2018). Overall,
326 the annual mean rainfall climatology from IMERG compares well with the IMD rain gauge dataset.
327 However, the overestimation of rainfall in the Indo-Gangetic plains and parts of northeast India
328 and underestimation of rainfall over the northern Western Ghats, northern sections of northeast
329 India, and the bulk of Jammu and Kashmir by IMERG relative to IMD dataset is apparent (Fig. 1).
330 Bushair et al., (2019) noted that IMERG underestimates the rainfall over high-altitude regions
331 compared to IMD observations, which are rain gauge based. Further, Fig. 1d shows the cumulative
332 rainfall anomaly curve generated from the 23-year (2001 - 2023) daily rainfall climatology area
333 averaged over all of India for IMERG (blue) and IMD (red) observations. The onset (inflection at
334 the nadir of the cumulative anomaly curve) and withdrawal (inflection at the zenith of the
335 cumulative anomaly curve) dates estimated from IMERG and IMD closely match each other, with
336 the onset dates being 31st May and 3rd June, and the withdrawal dates being 7th October and 8th
337 October, respectively.

Deleted: demise

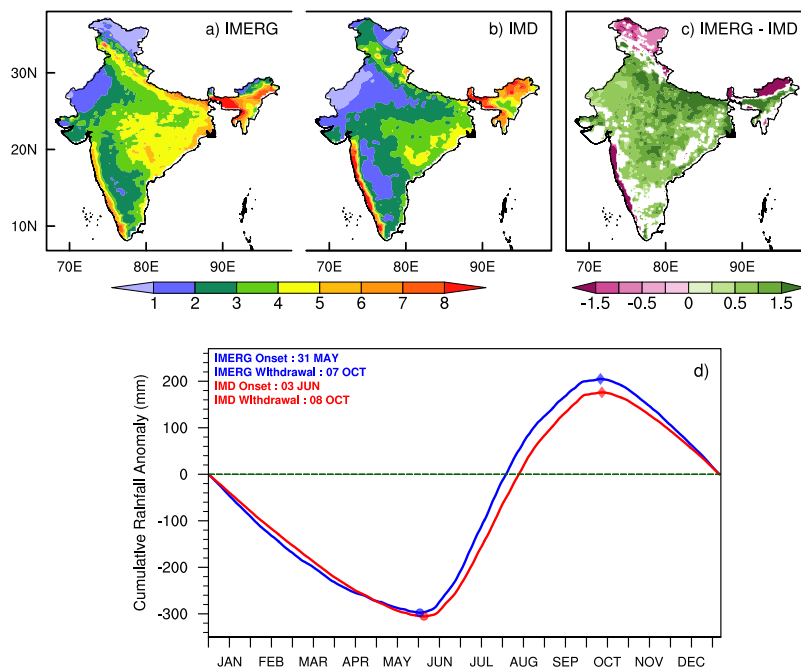

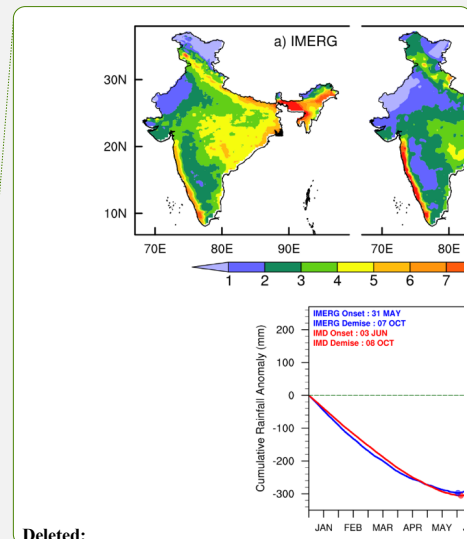

Figure 1: Spatial pattern of the 23-year climatology of the mean annual rainfall (mm/day) during the period 2001-2023 from a) IMERG observation, b) IMD observation, and c) the difference between the IMERG and IMD (only differences significant at 5% percentile level on t-test is shaded). d) The cumulative rainfall anomaly curve generated from the 23-year daily rainfall climatology of IMERG (blue) and IMD (red) observations. The onset dates (filled circles) and withdrawal dates (filled diamonds) obtained from both datasets are marked.

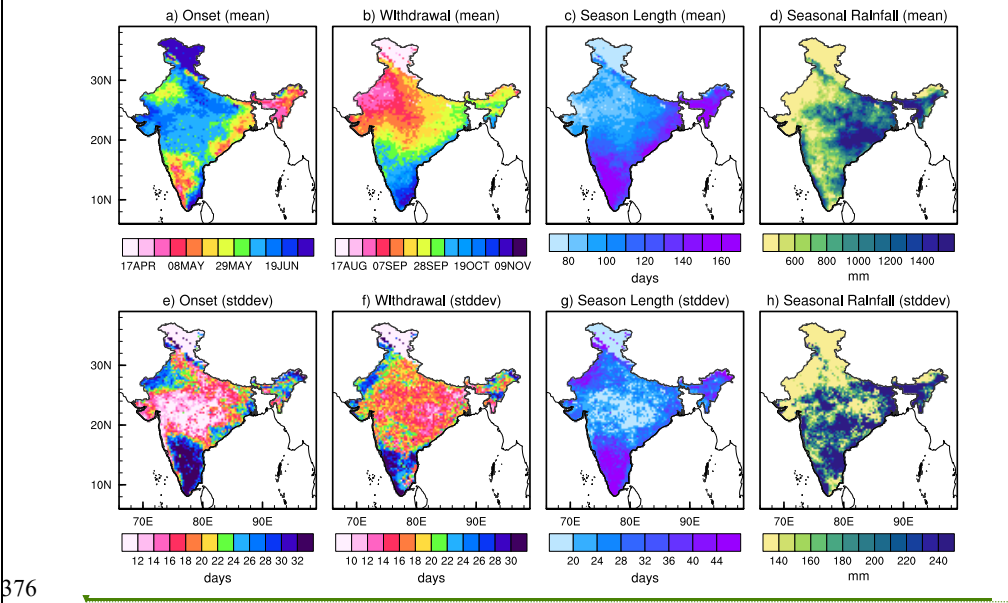

Figures 2a-d depict the 23-year local climatological onset date, withdrawal date, seasonal length, and seasonal accumulated rainfall from IMERG, with the associated standard deviation displayed in Figs. 2e-h. The spatial distribution of the climatology of the onset dates (Fig. 2a) shows the earliest onset occurs over northeast regions of India followed by southern Kerala, and then it gradually advances to the other parts of the country and looks like the typical isochrone evolution of the ISM (Ramage 1971; Rao 1976; Janowiak and Xie 2003). The delayed onset occurs over the east coast of Tamil Nadu followed by Jammu and Kashmir. The onset dates over Kerala and

Deleted: demise

Deleted: demise

360 adjacent regions mostly start from early May and do not coincide with the MoK, and this is because
361 this methodology detects the onset dates relatively early due to strong and continuous spells of
362 pre-monsoon rainfall. Similarly, the earliest withdrawal (Fig. 2b) of the ISM occurs over
363 northwestern India such as Rajasthan, Punjab, Haryana, and Himachal Pradesh. The withdrawal
364 date is delayed over southern peninsular India, with the most delayed withdrawal occurring over
365 the southeast coast of Tamil Nadu. The seasonal length (Fig. 2c) is shorter in the west and
366 northwest regions of India, with the shortest season in Jammu and Kashmir. The longer season
367 over the peninsular India, as well as the coastal regions of Odisha and West Bengal, is linked to
368 the season's earlier start date. The spatial distribution of the seasonal accumulated rainfall (Fig.
369 2d) closely follows the typical seasonal mean ISM distribution. The standard deviation patterns of
370 the onset dates show central parts of India have less variability than other regions, such as southern
371 peninsular India, northeast, and northwest regions. Similar patterns of variability are observed in
372 the withdrawal dates and seasonal length with the largest variations found over southern peninsular
373 India and northwest India and least over central India. On the other hand, the seasonal rainfall
374 exhibits a significant range of variability across most of India, whereas comparatively less
375 variability is observed over Rajasthan and Jammu and Kashmir.

Figure 2: The climatological a) onset date (Julian day), b) withdrawal date (Julian day), c) seasonal length, and d) seasonal accumulated rainfall (mm) of the rainy season from IMERG. The corresponding standard deviation of e) onset date (days), f) withdrawal date (days), g) seasonal length (days), and h) seasonal accumulated rainfall (mm). The contour intervals in panels (a) and (b) are at 7-day interval.

The IMERG dataset, with its 23-year record, was compared to the IMD and CPC datasets spanning 1979–2023 (limited to this period in order for CPC and IMD to have a common period) to evaluate onset and withdrawal dates, seasonal length, and seasonal accumulated rainfall of the rainy season over India (Fig. S2). The motivation to carry out this comparison is to establish that a 23-year record of IMERG is comparable to a longer record of dataset available from the other two sources besides examining its fidelity.

It is apparent from Fig. S2 that the spatial patterns of the climatological onset and withdrawal dates, seasonal length, and rainfall in IMERG is comparable to corresponding climatologies from IMD and CPC datasets. There is however a tendency for IMERG to have a bias of a slightly earlier onset of the rainy season compared to IMD and CPC, particularly over southern peninsular India, including Kerala and Tamil Nadu (Figs. S2a-c). Similar inference can be drawn in Rajasthan, coastal Odisha and West Bengal, and few isolated grid points over other regions. In contrast, over Jammu and Kashmir, IMERG exhibits a noticeably delayed onset, which makes us unsure about the results over this area. Similarly, IMERG display a systematic bias of slightly later withdrawal dates along the Western Ghats, but overall, the rainy season withdrawal dates are consistent across datasets (Figs. S2e-g). As a result, IMERG's rainy season seems to last longer than the other two datasets in some of these locations (Figs. S2i-k). Again, in terms of seasonal accumulated rainfall (Figs. S2m-o), IMERG overestimates precipitation compared to IMD and CPC in some of these locations. However, rainfall over the Western Ghats exhibits stronger gradients and is underestimated in IMERG while it exhibits more rainfall over western central India and Tamil Nadu than the other two datasets.

The interannual variability of these variables in IMERG also appear to be comparable to the other two datasets, especially in their spatial gradients (Fig. S3). There are however instances of some

Deleted: Fig. S2j-l

428 differences in the datasets. For example, over central India, the standard deviation of seasonal
 429 rainfall is significantly overestimated in IMERG compared to IMD (Figs. S3m-o), even though
 430 the withdrawal dates (Figs. S3e-g) and seasonal length (Figs. S3i-k) exhibit less variability in
 431 IMERG.

432
 433 As mentioned earlier, IMERG has few different rainfall products based on the latency of their
 434 availability in real-time. We have made comparisons of 12-hour latency product with the Final
 435 product of IMERG in Figs. S1, S2, and S3. The comparison in Fig. S1 indicates that some of the
 436 largest differences in the seasonal rain of the variable rainy season between Final and 12-hour
 437 latency of IMERG is over northern India. However, the spatial patterns of the climatological onset
 438 appear comparable (Figs. S2c and d). But the climatological withdrawal dates appear to be slightly
 439 earlier in northern India in the Final run (Fig. S2h) compared to 12-hour latency (Fig. S2g) of
 440 IMERG, which likely leads to slightly shorter length (Fig. S2l) and reduced seasonal rainfall (Fig.
 441 S2p) in the former (Fig. S2l) than in the latter (Figs. S2k and o). Some of the discrepancies
 442 observed in the 12 hour latency product of IMERG relative to IMD and CPC in Figs. S2 and S3
 443 can likely be attributed to the uncertainty associated with the choice of the 12-hour latency product,
 444 which is an early version of IMERG with limited calibration against ground-based observations,
 445 its shorter temporal coverage of 23 years compared to the 45 years of data used for IMD and CPC.
 446 Despite these limitations, which seem to be tolerable for the applications of this study (compare
 447 Fig. 1) we are inclined to use IMERG due to its higher spatial resolution and near real-time
 448 availability making it particularly suitable for real-time applications.

449
 450 The primary motivation to monitor the local onset and withdrawal of the ISM is its significant
 451 interannual variations and spatial variability (Fig. S3). Both the variation in seasonal length and
 452 seasonal rainfall are crucial in determining the nature of the rainy season (Xavier et al.
 453 2007; Sperber and Annamalai 2014). The spatial distribution of the correlation of the local onset
 454 date with the seasonal length shows a significant negative correlation across India except in some
 455 parts of central India and Jammu and Kashmir (Fig. 3a). This negative correlation suggests that an
 456 early or later onset date is likely to be associated with a longer or a shorter rainy season,
 457 respectively. Only the correlations significant at a 5% level are shaded (non-significant values are
 458 shown in white) in Fig. 3. Similarly, early onset is associated with a wetter season, while a delayed

474 onset is linked with a drier season (Fig. 3b). However, the grid points showing significant
475 correlation are fewer in Fig. 3b compared to Fig. 3a. The correlations of the withdrawal date with
476 seasonal length (Fig. 3c) and seasonal rainfall anomalies (Fig. 3d) show that later or early
477 withdrawal of the wet season corresponds to a longer and wetter season, whereas an earlier
478 withdrawal corresponds to shorter and drier seasons. While the correlation between seasonal
479 rainfall and onset/withdrawal dates appears weaker than that with seasonal length, over 50% of
480 grid points across India still show statistically significant relationships. This is expected, as total
481 rainfall during the rainy season is influenced by variations in the seasonal length but also daily rain
482 rate, which can be influenced by various factors like tropical cyclones and intraseasonal weather
483 patterns that may lead to a weak correlation with onset/withdrawal dates. However, the withdrawal
484 date may not be a useful predictor for the rainy season because it occurs when the rainy season
485 ends. The onset and withdrawal dates are largely uncorrelated, (not shown), implying that their
486 variations are independent of each other. These outcomes imply that the onset date alone can be a
487 useful predictor for the outlook of the seasonal length and the seasonal rainfall anomaly of the
488 forthcoming rainy season.

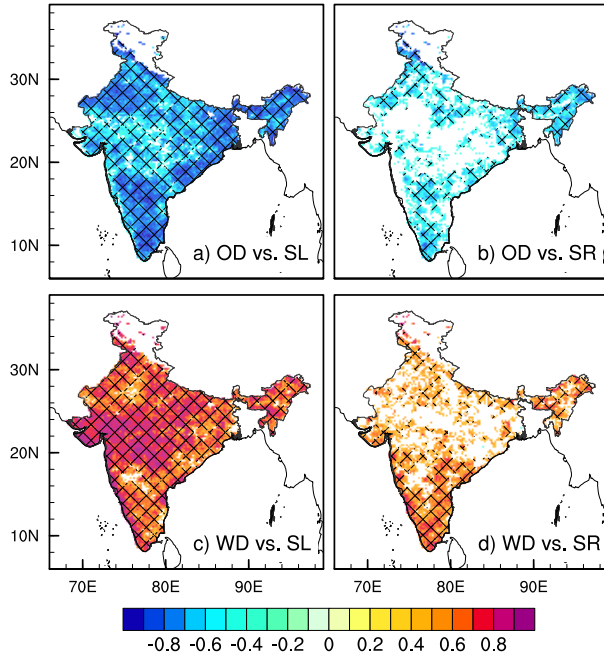

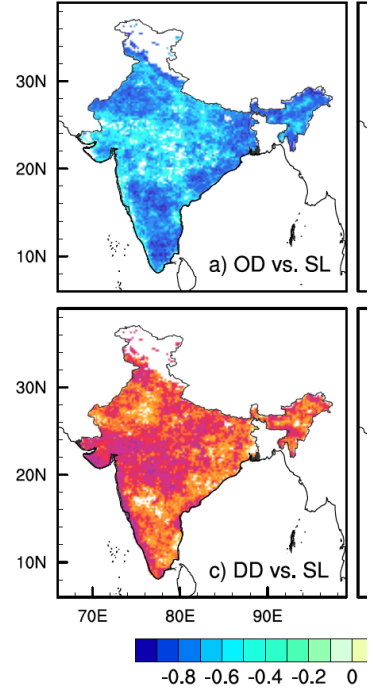

Figure 3: The correlation coefficients of the onset date (OD) with a) seasonal length (SL), and b) seasonal rain (SR). Similarly, the correlations of withdrawal date (WD) with c) SL and d) SR. The shading indicates statistical significance at a 5% significance level according to the *t*-statistic, (non-significant values are shown in white), following false discovery rate testing as described by Benjamini and Hochberg (1995). Cross hatchings denote correlations greater than or equal to ± 0.6 .

We estimated the signal-to-noise ratio (Equation 4) on the four variables of onset and withdrawal dates, seasonal length, and rainfall by utilizing the 101-member ensemble of time-series data. This analysis examines the spread across ensemble members and informs on the uncertainty of the diagnosis to random rain events. The signal-to-noise ratio for onset dates (Fig. 4a) shows that noise dominates in many places, particularly in peninsular India and the eastern half of central India. These low signal-to-noise ratio regions suggests that onset dates of the rainy season are not very strongly tied to the seasonal cycle and predicting the onset dates in these places becomes challenging and less reliable. In contrast, the signal-to-noise ratios for withdrawal dates (Fig. 4b)

Deleted:

Deleted: DD

Deleted: ,

Deleted: demise

are typically more than one over most grid points. This indicates greater certainty for withdrawal dates, particularly in areas like Kerala, coastal Karnataka, and Gujarat, where the ratios are comparatively higher than one. In the case of the seasonal length, signal dominates over noise with a signal-to-noise ratio above 1 over most areas (Fig. 4c). Compared to the other variables, seasonal rainfall generally shows much higher signal-to-noise ratios (> 1) across most of the grid points. This result is obvious given the fact that seasonal rainfall is an aggregate of the daily rainfall over the entire rainy season, while the onset and withdrawal dates are single days of the season when they are diagnosed. Therefore, there is a tendency for the cancellation of the noise in the aggregation of the daily rainfall to seasonal rainfall, which yields a higher signal-to-noise ratio.

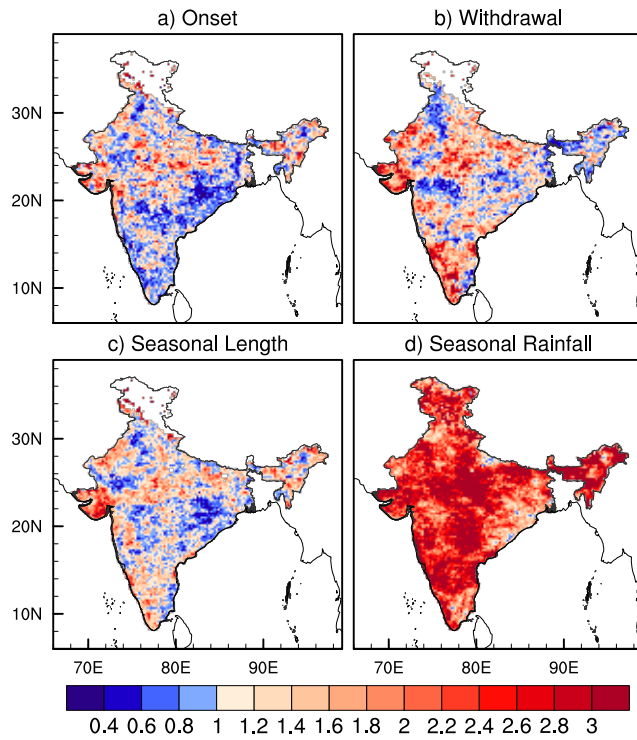

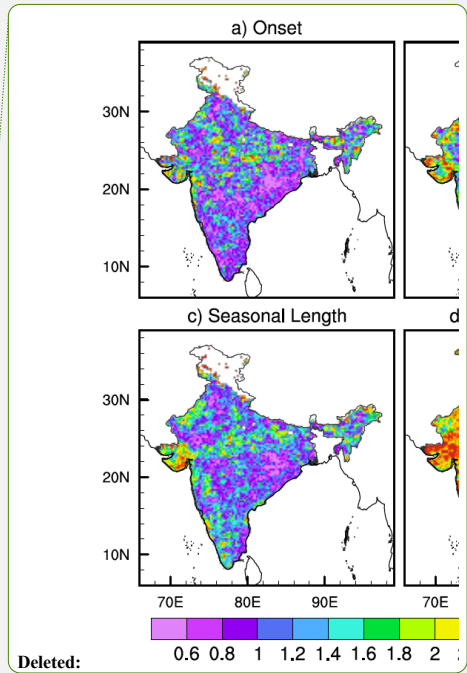

Figure 4: The 23-year climatology of the signal-to-noise ratio of a) onset date, b) withdrawal date, c) seasonal length, and d) seasonal rainfall estimated based on the 101 ensemble members.

534 Further, we examined the probabilistic skill of the seasonal outlook by using the Area Under the
 535 relative operating characteristic (ROC) Curve (AUC) method. The AUC method is widely used to
 536 assess the skill of seasonal climate predictions (Mason and Graham 2002; Misra 2004; Narotsky
 537 and Misra 2021). Previous studies have shown that this method is useful for evaluating the
 538 probabilistic skill of predicting anomalous seasons based on anomalous onset dates of the rainy
 539 season (e.g. Rodgers et al 2024). We categorized the onset date, seasonal length, and seasonal
 540 rainfall into terciles (23-years divided into three groups): the lower tercile represents an early onset,
 541 shorter season, and drier conditions; the upper tercile signifies a delayed onset, longer season, and
 542 wetter conditions; and the middle tercile indicates normal onset, length, and seasonal rainfall. We
 543 then created a contingency table (Table S1) to assess the probability of categorical forecasts. This
 544 table evaluates how often an early or late onset is linked with a shorter or longer season and with
 545 drier or wetter conditions, respectively. In addition, we also consider the effects of normal onset
 546 on normal length and seasonal rainfall.

547
 548 **Figure 5:** The probabilistic skill score as measured by the Area Under the relative operating
 549 characteristic Curve (AUC) for early start (lowest tercile) season associated with a) longer

(highest tercile) and b) wetter (highest tercile) season, late start (highest tercile) season associated with c) shorter (lowest tercile) and d) drier (lowest tercile) season, and normal (middle tercile) start season associated with e) normal (middle tercile) seasonal length and f) normal (middle tercile) seasonal rain. The AUC above 0.5 is shaded.

The probabilistic skill scores derived from the AUC method are shown in Fig. 5. Here, only grid points with AUC values ≥ 0.5 are shaded, as these points indicate skillful seasonal outlooks that outperform random predictions (Mason and Graham, 2002). The seasons with an early start and longer season (Fig. 5a) show the most skill (>0.9) over peninsular India, northwest India, and some parts of northeast India. Similarly, the early start of the season, along with the wetter season (Fig. 5b), results in high skill levels across most parts of India except the majority of Maharashtra and north interior Karnataka. The late start and associated shorter seasons shown in Fig. 5c exhibit the highest skill score over some parts of peninsular India. The late start with the drier season also resulted in high skill scores across most of the areas except Kerala, Tamil Nadu, Karnataka and Andhra Pradesh. The anomalous seasons (Fig. 5a-d) demonstrate higher skill levels across India compared to the normal seasons (Fig. 5e-f). This is due to the leveraging of the linear relationships of the onset date variations with the rainy season variations (Figs. 3a and b). In contrast, seasons with a normal start of the rainy season exhibit lower AUC skill scores (Figs. 5e and f) across most grid points relative to the anomalous start of the rainy seasons (Figs. 5a-d). However, the skill scores for a normal start with normal rainfall (Fig. 5f) are slightly better than those for a normal start with normal length (Fig. 5e). In summary, the behavior of the forthcoming season is more predictable if the onset date is early or delayed than the normal. It is easy to adopt this methodology for real-time applications. The evolution of the daily cumulative anomaly curve of rainfall could be monitored in real-time to find the minima in the curve as the onset date. However, to avoid misdiagnosing the onset date of the rainy season, one could wait for a period of time after this diagnosis (typically a week) to confirm that the minima were indeed reached to declare the onset date. Once the onset date is diagnosed then one could use the linear relationships shown in Fig. 3 to develop a seasonal outlook for the rainy season. This is done routinely in Florida (Misra et al. 2022). With the availability of the merged IMERG estimates with the rain-gauge based IMD rainfall following Mitra et al., (2009) our proposed methodology could be adopted for real-time applications over India.

581
582 Further, we investigated the interannual variability of the onset dates over India and its association
583 with ENSO (Figure S4) and the Indian Ocean Dipole (IOD) variations (Figure S5). In comparison
584 to Figure 3, Figures S4 and S5 failed the BH test suggesting the lack of robustness in the
585 teleconnections of the rainy season variations with either ENSO or IOD. It should be noted that
586 the results in Figures S4 and S4 appear to be contrary to many other studies that suggest a robust
587 teleconnection of ENSO with ISM (e. g., Webster et al. 1998, Delsole and Shukla 2002). However,
588 our variable definition of the rainy season which includes pre- and post-monsoon rainfall would
589 make the comparison with other studies dealing with fixed calendar ISM season and or all India
590 averaged rainfall of the ISM incompatible. But in light of these results that indicate a lack of strong
591 external forcing, the significance of the reliability of the seasonal outlook of the rainy season
592 shown in Figure 5 assumes greater significance. Furthermore, the monitoring of the observations
593 of the evolution of the rainy season to diagnose the onset dates seems an attractive approach with
594 the relatively low signal-to-noise ratio of the onset date of the rainy season shown in Figure 4a
595 relative to the seasonal length in Figure 4c or seasonal rainfall in Figure 4d. We are then able to
596 leverage a low signal-to-noise ratio quantity like the onset date of the rainy season to provide a
597 seasonal outlook of relatively higher signal-to-noise ratio quantities of seasonal length and rainfall.

599 4. Summary and Concluding Remarks

600 The seasonal prediction of the Indian rainy season is a considerable challenge given its complex
601 spatio-temporal variations. In this study, we offer a simple and reliable technique for seasonal
602 outlook of the rainy season, which is viable for real-time applications as well. Using precipitation
603 estimates of IMERG version 6 over India at 10km grid, we generate an ensemble of 101 members
604 from randomly perturbing the series to assess the uncertainty of the diagnosed onset/withdrawal
605 dates of the rainy season to random synoptic-meso scale rain events unconnected to the seasonal
606 cycle. The proposed method generates a spatial distribution of local-scale onset and withdrawal
607 dates, capturing regional variations and offering a nuanced view of progression rainy season across
608 India. Such location-specific information is useful for practical applications such as agriculture,
609 disaster planning, and water management.

Deleted: demise

615 We verified the IMERG rainfall observations against gauge-based IMD observations. The mean
616 annual rainfall climatology of IMERG closely matches that of the IMD. However, IMERG tends
617 to underestimate mean annual rainfall in high-altitude regions and overestimate it in the Indo-
618 Gangetic plains. Further, we examined the relationships between the onset and withdrawal dates
619 with seasonal length and rainfall and discovered that variations in onset and withdrawal dates of
620 the rainy season across India have a significant impact on the seasonal length and the seasonal
621 rainfall variations of the rainy season. It is found that an earlier onset date of the rainy season is
622 strongly related to a longer and wetter season, whereas a later onset date corresponds to a shorter
623 and drier season. However, the relationship between the onset, withdrawal, seasonal length, and
624 rainfall with large-scale climate drivers such as ENSO and IOD is comparatively weaker in major
625 parts of India. Although the influence of ENSO and IOD were investigated in this study, future
626 research could investigate the influence of additional teleconnection patterns such as the Madden–
627 Julian Oscillation (MJO), Pacific Decadal Oscillation (PDO), and North Atlantic Oscillation
628 (NAO), which may also modulate the timing and characteristics of the rainy season.

630 This study shows that by estimating the onset date of the rainy season alone we can effectively
631 provide a reliable seasonal outlook for both the seasonal length and total rainfall of the upcoming
632 season by exploiting the existing local relationships. The low signal to noise ratio of the onset date
633 of the rainy season suggests the dominance of internal variations, which will be a challenge for its
634 seasonal predictability. However, by way of monitoring the evolution of the onset date we can
635 leverage its local relationship with the length and seasonal rainfall anomaly to provide reliable
636 seasonal outlook of the rainy season. The probabilistic skill scores of these seasonal outlooks
637 generated from the monitoring of the onset date variations present an objective measure of its high
638 confidence of reliability. Compared to traditional ISM onset definitions, which often focus on
639 Kerala (e.g., MoK), the proposed method can generate spatial maps of local-scale onset dates of
640 the rainy season. It captures regional heterogeneity and the progression of the rainy season across
641 India. Since the method is based on the rainy season and includes pre- and post-monsoon rainfall,
642 it provides a comprehensive viewpoint of the rainy season. These seasonal outlooks have
643 numerous potential applications, and many local communities could greatly benefit from them.
644 The proposed methodology for the seasonal outlook of the rainy season over India demonstrates
