Abstract. Gravitational separation of gas species in the stratosphere is caused mainly by molecular diffusion and is a powerful tool to diagnose stratospheric transport processes. Previous studies have shown that isotopic and elemental ratios of major atmospheric components decrease with increasing altitude in proportion to the differences of their mass numbers. However, there have been no reports of the vertical changes of Kr, Xe, and Ne in the stratosphere. Here we report the results of the first study of the vertical changes of Kr, Xe, and Ne in the stratosphere based on high-precision analyses. Our goal was to reveal the vertical distributions of noble gases and to clarify the mechanisms governing their separations. Noble gases were measured for the stratospheric air collected by balloon-borne cryogenic air samplers over Japan. We found that the isotopic and elemental ratios of all noble gases decreased and increased with increasing altitude for heavy and light noble gases, respectively. Vertical distributions normalized for the mass number differences indicated that the larger the mass number, the smaller the separation of both the isotopic and elemental ratios. The implication was that kinetic fractionation occurred in the stratosphere because of the differences of molecular diffusivities. We performed model simulations and were able to reproduce the kinetic fractionations for heavier noble gases. Results of model simulations suggested that the kinetic fractionations of noble gases were usable as a new tool to diagnose stratospheric transport processes. In the modern atmosphere, it is difficult to detect the long-term change of the stratospheric circulation from noble gases, except for Ar/N₂ ratio, in the troposphere. However, it was suggested that changes in the stratospheric circulation during glacial and interglacial cycles may have affected the noble gas elemental ratios in ice core samples.

1 Introduction

Earth's atmosphere contains noble gases, which are extremely stable substances. Argon accounts for approximately 0.9 % of the atmosphere by mole fraction and is one of the major constituents of the atmosphere. The other noble gases — He, Ne, Kr, and Xe — exist in the atmosphere, but their mole fractions are very small. Since noble gases are extremely stable

35 in the atmosphere, their mole fractions can be considered to be almost constant temporally and uniform spatially. ^{40}Ar is
36 released from Earth's crust into the atmosphere through radioactive decay of ^{40}K , but the amount released is extremely
37 small compared to the amount present in the atmosphere (Bender et al., 2008). It can therefore also be considered to have
38 a constant mole fraction in the modern atmosphere. Recent progress in ultra-high-precision analysis has enabled the
39 detection of extremely small variations of the isotopic and elemental ratios of noble gases (Severinghaus et al., 2003;
40 Severinghaus and Battle, 2006; Kawamura et al., 2013; Bereiter et al., 2018a; Oyabu et al., 2025). The possible separation
41 of the noble gases and the major constituents in the atmosphere is generally related to molecular diffusion, which is
42 predominant only in the upper atmosphere above the turbopause and in the air within the firn layer on the surface of polar
43 ice sheets. In both cases, the region is characterized by competition between molecular and eddy diffusion.

44 In the firn layer, air transport through tortuous open pores is governed mainly by molecular diffusion. The separation
45 of the constituents of the air therefore occurs in proportion to the differences of their mass numbers if the isotopic or
46 elemental ratios in the atmosphere are constant and there are no disturbances caused by eddy diffusion and/or thermal
47 inhomogeneity within the firn. This process is generally called gravitational separation. Under such conditions, the
48 isotopic ratios of $^{29}\text{N}_2/^{28}\text{N}_2$ and $^{34}\text{O}_2/^{32}\text{O}_2$ in the firn air increase almost linearly with increasing depth, and the magnitude
49 of separation of $^{34}\text{O}_2/^{32}\text{O}_2$ is about twice that of $^{29}\text{N}_2/^{28}\text{N}_2$ (e.g., Schwander et al., 1989; Sowers et al., 1989). At the bottom
50 of the firn layer, air in the open pores is gradually trapped into bubbles in the ice. The component of the air in the ice-core
51 bubbles is altered by this gravitational separation. There are also slight changes because of thermal and eddy diffusion
52 and fractionations that depend on the mass and diameter of the molecule during the bubble formation (Severinghaus and
53 Battle, 2006; Battle et al., 2011). Measurements of various gases in firn air thus provide information that facilitates
54 understanding the process of fractionation during bubble formation and, consequently, the interpretation of the gas
55 component in ice cores.

56 The processes of advection and eddy diffusion are much more important than molecular diffusion in the troposphere
57 and stratosphere, and it has generally been assumed that molecular diffusion could be ignored at altitudes below about
58 100 km. The motivation for this study was the discovery in our previous work of the gravitational separation of major
59 atmospheric components in the stratosphere (Ishidoya et al., 2013). Before this discovery, it was commonly assumed that
60 the major atmospheric components and noble gases were uniformly distributed in the troposphere and stratosphere and
61 that their molecular diffusion was an insignificant phenomenon. Their fractionation was assumed to be difficult to detect
62 because of molecular diffusion below the turbopause, except under the special conditions within the lowermost boundary
63 layer (Adachi et al., 2006). Bieri et al. (1970) measured mole fractions of Ne, Ar, and Kr in the upper stratosphere and
64 lower mesosphere by using a rocket-borne cryogenic air sampler and concluded that their mole fractions were identical
65 to those in surface air, that the atmosphere was very well mixed up to the lower mesosphere, and that gravitational
66 separation was too small to be detected. Ehhalt et al. (1975) also measured mole fractions of Ar, Kr, and Xe in the upper
67 stratosphere and showed that their mole fractions were not significantly different in stratospheric and surface air. However,
68 high-precision analytical techniques have recently made it possible to detect even slight separations of major atmospheric
69 components in the stratosphere. The gravitational separation of major atmospheric components in the stratosphere was
70 first reported by Ishidoya et al. (2006). They showed that the variations with altitude of the isotopic and elemental ratios

71 of the major atmospheric components were caused by differences of molecular mass (Ishidoya et al., 2008a, 2008b, 2013).
72 This explanation was consistent with the mass-dependent relationships among the related molecules such as the ratios of
73 $^{28}\text{N}_2/^{29}\text{N}_2$, $^{32}\text{O}_2/^{34}\text{O}_2$, and $^{40}\text{Ar}/^{28}\text{N}_2$. These mass-dependent fractionations in the stratosphere were similar to those
74 observed in firn air, even though the effects of advection and eddy diffusion far exceed those of molecular diffusion in
75 the stratosphere. Understanding of gravitational separation in the stratosphere has been enhanced by various
76 observations (Ishidoya et al., 2013; 2018; Sugawara et al., 2018) and studies using numerical models (Belikov et al.,
77 2019; Birner et al., 2020). However, the mechanisms and roles of molecular diffusion processes in the stratosphere are
78 not fully understood, mainly because of a lack of relevant data for constituents other than O_2 , N_2 , and Ar in the stratosphere.

79 The discovery of gravitational separation in the stratosphere led us to hypothesize that similar separations would occur
80 in the isotopic and elemental ratios of noble gases in the stratosphere. Actually, measurements of the properties of noble
81 gases in firn air have been conducted and have provided useful information about firn air and bubbles in ice cores
82 (Severinghaus and Battle, 2006; Battle et al., 2011; Kawamura et al., 2013; Buizert et al., 2023; Oyabu et al., 2025).
83 However, with the exception of Ar , there have been no observations of noble gases in the stratosphere. In this study, we
84 report the vertical distribution of noble gases in the stratosphere for the first time, and we discuss the properties associated
85 with molecular diffusion of noble gases in the stratosphere by incorporating the results of numerical models. The main
86 objective of this study was to clarify the mechanisms governing the variation of the properties of noble gases and to
87 understand the processes associated with molecular diffusion in the stratosphere. Understanding the variations of the
88 properties of noble gases in the stratosphere was expected to be greatly facilitated by knowledge derived from studies of
89 firn air. This paper focuses on the similarities and differences between the fractionations in firn air and the stratosphere
90 and discuss disequilibrium fractionation and its role in stratospheric processes.

91 **2 Experimental Procedure**

92 **2.1 Sampling stratospheric air**

93 We have continued to collect samples of stratospheric air over Japan since 1985 using balloon-borne cryogenic samplers
94 (e.g., Nakazawa et al., 1995). In this study, we analyzed air samples obtained from balloon observations during June 2007
95 and July 2020. Air samplers were launched from the Sanriku Balloon Center ($39^{\circ}10'\text{N}$, $141^{\circ}50'\text{E}$) in Iwate Prefecture in
96 2007 and the Taiki Aerospace Research Field ($42^{\circ}30'\text{N}$, $143^{\circ}26'\text{E}$) in Hokkaido Prefecture in 2020. Each cryogenic air
97 sampler was equipped with a liquid helium dewar, stainless steel bottles, motor-driven valves, and a control unit (Honda
98 et al., 1996). Liquid helium was used as a refrigerant to enable us to collect stratospheric air cryogenically. We were thus
99 able to collect a large amount of air (20–30 L at standard temperature and pressure) in each bottle. Air samples were
100 collected at 10 different altitudes between 14.5 and 32.8 km during 2007 and at 11 altitudes between 14.8 and 35.4 km
101 during 2020. Approximately two-thirds of the sample air in each bottle was immediately used for measurements of the
102 mole fractions and isotopic ratios of various gases, and one-third was transferred into another stainless-steel container
103 with a volume of 300 mL for long-term archiving and possible use in future studies. We used archived samples of air
104 collected in 2007 for the noble gas measurements. The air samples collected in 2020 were directly aliquoted from each

105 bottle into two 550-mL Pyrex glass flasks at atmospheric pressure and used for analysis of noble gases. Because analyses
106 were performed twice for each air sample collected in 2020, the average value was calculated and used for data analysis.

107 **2.2 Noble gas measurements**

108 Table 1 summarizes the isotopic and elemental ratios measured in this study. Isotopic and elemental ratios of noble
109 gases— $\delta(^{40}\text{Ar}/^{36}\text{Ar})$, $\delta(^{40}\text{Ar}/^{38}\text{Ar})$, $\delta(^{38}\text{Ar}/^{36}\text{Ar})$, $\delta(^{86}\text{Kr}/^{82}\text{Kr})$, $\delta(^{86}\text{Kr}/^{83}\text{Kr})$, $\delta(^{86}\text{Kr}/^{84}\text{Kr})$, $\delta(^{132}\text{Xe}/^{129}\text{Xe})$, $\delta(^{136}\text{Xe}/^{129}\text{Xe})$,
110 $\delta(^{136}\text{Xe}/^{132}\text{Xe})$, $\delta(^{84}\text{Kr}/^{40}\text{Ar})$, $\delta(^{132}\text{Xe}/^{40}\text{Ar})$, and $\delta(^{22}\text{Ne}/^{40}\text{Ar})$ —were measured at the National Institute of Polar Research
111 (NIPR; Tachikawa, Japan). For example, the isotopic ratio of ^{40}Ar and ^{36}Ar was defined as

$$112 \delta(^{40}\text{Ar}/^{36}\text{Ar}) = \frac{[n(^{40}\text{Ar})/n(^{36}\text{Ar})]_{sp}}{[n(^{40}\text{Ar})/n(^{36}\text{Ar})]_{rf}} - 1, \quad (1a)$$

113 where “n”, “sp”, and “rf” denote the abundance of the respective component, the sample, and the reference gas,
114 respectively. The isotopic ratios for Ar, Kr, and Xe were defined in a similar manner. The elemental ratio of ^{84}Kr to ^{40}Ar
115 was defined as

$$116 \delta(^{84}\text{Kr}/^{40}\text{Ar}) = \frac{[n(^{84}\text{Kr})/n(^{40}\text{Ar})]_{sp}}{[n(^{84}\text{Kr})/n(^{40}\text{Ar})]_{rf}} - 1. \quad (1b)$$

117 Because the other elemental ratios were defined similarly, their notations are omitted here. These δ values are usually
118 expressed in per meg (1 per meg is 0.001 ‰). For air samples collected in 2007, we measured $\delta(^{40}\text{Ar}/^{36}\text{Ar})$, $\delta(^{40}\text{Ar}/^{38}\text{Ar})$,
119 $\delta(^{38}\text{Ar}/^{36}\text{Ar})$, $\delta(^{86}\text{Kr}/^{82}\text{Kr})$, $\delta(^{86}\text{Kr}/^{83}\text{Kr})$, $\delta(^{86}\text{Kr}/^{84}\text{Kr})$, $\delta(^{84}\text{Kr}/^{40}\text{Ar})$, and $\delta(^{132}\text{Xe}/^{40}\text{Ar})$. For air samples collected in 2020,
120 we also measured $\delta(^{132}\text{Xe}/^{129}\text{Xe})$, $\delta(^{136}\text{Xe}/^{129}\text{Xe})$, $\delta(^{136}\text{Xe}/^{132}\text{Xe})$, and $\delta(^{22}\text{Ne}/^{40}\text{Ar})$. Because the analytical method for the
121 noble gases has been described elsewhere (Severinghaus et al., 2003; Severinghaus and Battle, 2006; Kawamura et al.,
122 2013; Bereiter et al., 2018a; Oyabu et al., 2025), only a brief description is presented here.

123 The archived air was stored in a stainless-steel container pressurized to approximately 20 bar and equipped with a
124 bellows seal valve (Swagelok SS-8BG). An additional bellows seal valve was attached to the existing valve, and an 80-
125 mL glass flask was connected. After evacuation, an aliquot of the sample was first isolated within the pipette volume
126 between the bellows seal valves and then expanded into the evacuated 80-mL glass flask. For the samples collected in
127 2020, a 550-mL glass flask was connected to the 80-mL glass flask. After evacuation, the air sample was expanded into
128 the 80-mL flask. For the ground-surface values, atmospheric air was sampled outside the NIPR building (hereafter,
129 “Tachikawa air”) in 1500-mL glass flasks using an established method (Oyabu et al., 2020). The 1500-mL flask was
130 connected to the evacuated 80-mL flask, and the air sample was expanded. For the measurements of samples collected in
131 2020, Tachikawa air was collected in the same 550-mL glass flasks used for stratospheric samples. The same analytical
132 procedures were applied to both the stratospheric and Tachikawa air samples to eliminate potential fractionation caused
133 by sample splitting. No statistically significant differences were observed between the results obtained using the 1500-
134 mL and 550-mL flasks.

135 The air sample split into the 80-mL flask was exposed to Zr/Al SAES getters at 900°C for 30–40 min to remove all

136 the N₂, O₂, and other reactive gases, followed by an additional 10 min at 300°C to remove H₂ gas. The gettered air was
 137 then transferred into a sample tube inserted into a He cycle cooler at temperatures below 10 K for 15 min. After that
 138 transfer, the residual pressure in the vacuum line was measured. For the stratospheric air samples, the residual pressures
 139 were found to be 2.5–20 times those of Tachikawa air. Most of the residual gas consisted of He, which was considered to
 140 be a contaminant introduced during the balloon observation.

141 The isotopic and elemental ratios of Ar, Kr, Xe, and Ne were measured using a dual-inlet isotope ratio mass
 142 spectrometer (IRMS) (Thermo Fisher Scientific, MAT253). The $\delta(^{132}\text{Xe}/^{129}\text{Xe})$, $\delta(^{136}\text{Xe}/^{129}\text{Xe})$, and $\delta(^{136}\text{Xe}/^{132}\text{Xe})$ ratios
 143 were also measured with the MAT253 using a separate aliquot of the air sample. For the IRMS measurements, the
 144 integration time and idle time were 8 s and 12 s for the Ar isotopes and 26 s and 14 s for the Kr and Xe isotopes. We ran
 145 4 blocks of 16 changeover cycles (sample-standard changeover) for Ar isotopes (64 cycles total), 4 blocks of 25
 146 changeover cycles for Kr isotopes (100 cycles), and 9 blocks of 25 changeover cycles for Xe isotopes (225 cycles). The
 147 cycles were divided into four or nine blocks to enable adjustment of the bellows pressure. Without this adjustment, the
 148 pressure difference between the left and right bellows could increase over time and require a larger correction for the
 149 pressure imbalance. For the $\delta(^{84}\text{Kr}/^{40}\text{Ar})$, $\delta(^{132}\text{Xe}/^{40}\text{Ar})$, and $\delta(^{22}\text{Ne}/^{40}\text{Ar})$ measurements, we used a peak-jumping method
 150 in which the spectrometer magnet setting was sequentially switched between Kr and Ar, Xe and Ar, or Ne and Ar. Each
 151 changeover cycle consisted of a standard and sample measurement at the first magnet setting, followed by the same
 152 sequence at the second setting. The integration time was 8 s for each measurement. We performed 6 cycles for each
 153 isotope ratio, calculated a δ -value for each cycle, and reported the average of these six δ -values as the final value.

154 The reproducibility of the laboratory measurements was assessed using the pooled standard deviation (SD) of
 155 replicates (measurements made two or more times) for each sample. Table 1 summarizes the pooled SDs of the isotopic
 156 and elemental ratios. Isotopic and elemental ratios reported in this study were measured against reference gases and
 157 normalized against the ground surface values at Tachikawa, Tokyo. Isotopic and elemental ratios of the N₂, O₂, and Ar—
 158 $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$, $\delta(^{40}\text{Ar}/^{36}\text{Ar})$, and $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$ —were also measured at the National Institute of Advanced
 159 Industrial Science and Technology (AIST; Tsukuba, Japan) using IRMS. The technical details of our mass spectrometry
 160 analyses for major atmospheric components have been described by Ishidoya and Murayama (2014). The values of
 161 $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$, and $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$ are defined as

$$162 \quad \delta(^{29}\text{N}_2/^{28}\text{N}_2) = \frac{[n(^{29}\text{N}_2)/n(^{28}\text{N}_2)]_{sp}}{[n(^{29}\text{N}_2)/n(^{28}\text{N}_2)]_{rf}} - 1, \quad (2a)$$

$$163 \quad \delta(^{34}\text{O}_2/^{32}\text{O}_2) = \frac{[n(^{34}\text{O}_2)/n(^{32}\text{O}_2)]_{sp}}{[n(^{34}\text{O}_2)/n(^{32}\text{O}_2)]_{rf}} - 1, \quad (2b)$$

164 and

$$165 \quad \delta(^{40}\text{Ar}/^{28}\text{N}_2) = \frac{[n(^{40}\text{Ar})/n(^{28}\text{N}_2)]_{sp}}{[n(^{40}\text{Ar})/n(^{28}\text{N}_2)]_{rf}} - 1. \quad (2c)$$

166 Here, “rf” is the reference gas which is dried natural air filled in a high-pressure cylinder (cylinder no. CRC00045)

167 (Ishidoya and Murayama, 2014). Table 1 also shows the reproducibility of the $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$, $\delta(^{40}\text{Ar}/^{36}\text{Ar})$,
168 and $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$ measurements at AIST. The AIST data obtained by balloon observation in 2007 have been
169 published by Ishidoya et al. (2013).

170 The Ar isotopic ratios, $\delta(^{40}\text{Ar}/^{36}\text{Ar})$, of the air samples obtained by balloon observation and by sampling of firn air at
171 H128, Dronning Maud Land, East Antarctica were measured independently at NIPR and AIST (Ishidoya et al., 2013;
172 Oyabu et al., 2025) and compared with each other as shown in Figure 1. The values of $\delta(^{40}\text{Ar}/^{36}\text{Ar})$ were negative and
173 positive in the stratosphere and firn air, respectively, mainly because of the effects of gravitational separations. Because
174 molecular diffusion is dominant in firn air, the magnitude of fractionation was larger in firn air than in the stratosphere.
175 The $\delta(^{40}\text{Ar}/^{36}\text{Ar})$ values measured by AIST and NIPR were in good agreement in 2020, but there was a systematic
176 difference between the two measurements in 2007. The mean absolute difference of the values in 2007 was 50 ± 24 per
177 meg. Because the cause of this difference is currently unknown, we used both values in the data analysis.

178 Some data were significant outliers, probably because of fractionations during sample distribution and/or during the
179 time the samples were stored in bottles. We therefore fit the data to a linear function of altitude, and we iteratively excluded
180 outliers if the absolute values of their residuals exceeded 2σ . As a result, 29 data were excluded from a total of 296 data.

181 **2.3 Mean age of air**

182 Previous studies have shown that the gravitational separation of the major atmospheric components strengthens with
183 increasing altitude (δ values decrease with increasing altitude), and the mean age of stratospheric air increases
184 simultaneously. Therefore, it is known that the vertical distributions of $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$ and mean age of air show anti-
185 correlations (Ishidoya et al., 2013; Sugawara et al., 2018). These correlations have also been reproduced by 3-dimensional
186 model studies (Belikov et al., 2019; Birner et al., 2020). Furthermore, an anti-correlation in the interannual variations of
187 the gravitational separation and the mean age of air has been observed in the northern mid-latitude mid-stratosphere
188 (Ishidoya et al., 2013). This means that gravitational separation becomes stronger when the relevant stratospheric air
189 becomes older. The mean age of air has been estimated based on observation data of inert trace gases in the stratosphere.
190 If an inert tracer shows a linear trend in troposphere, the time lag between tropospheric and stratospheric mole fractions
191 is the mean age of air. The mole fractions of CO₂ and SF₆ have been widely used for this purpose, because both species
192 are almost inert in the stratosphere and show monotonous increase trends in troposphere. Therefore, we measured the
193 mole fractions of CO₂ and SF₆ in our stratospheric air samples and calculated the mean age of air as described below.
194 Because this method of estimation has already been described in previous studies (Umezawa et al., 2025; Sugawara et al.,
195 2025), only a brief description is presented here. The CO₂ mole fraction was measured with a nondispersive infrared gas
196 analyzer at Tohoku University with an analytical precision of less than 0.02 $\mu\text{mol mol}^{-1}$. Details about the CO₂
197 measurements have previously been reported (Nakazawa et al., 1995; Aoki et al., 2003; Sugawara et al., 2018). The SF₆
198 mole fraction was measured at Miyagi University of Education (Sendai, Japan) with a gas chromatograph equipped with
199 an electron capture detector with an analytical precision of less than 0.1 pmol mol^{-1} . Details of the SF₆ measurements
200 have been described by Sugawara et al. (2018). The mean age was estimated using the convolution method and the mole

201 fractions of CO₂ and SF₆ (e.g., Ray et al., 2014; Fritsch et al., 2020). The convolution method is a method for determining
 202 the mean age by calculating the convolution of the age spectrum and a tropospheric reference curve and comparing it
 203 with the observed value. Temporal variations of the CO₂ or SF₆ mole fractions in the stratosphere, $x(\Gamma, t)$, were calculated
 204 by convolution of the tropospheric reference curve, $x_0(t)$, and the hypothetical age spectrum, $G(\Gamma, t)$:

$$205 \quad x(\Gamma, t) = \int_{t-T_B}^t x_0(t') G(\Gamma, t-t') dt', \quad (3)$$

206 where T_B and $G(\Gamma, t)$ are the integration time interval and the age spectrum, respectively. The age spectrum is defined as
 207 the statistical probability of individual transit times of different air parcels arrived at a certain place in stratosphere after
 208 air parcels intruded into the stratosphere through the tropical upper troposphere. The age spectrum naturally changes over
 209 time, but it was ignored here. Because the actual age spectrum is usually unknown, we assumed that it could be
 210 approximated by an inverse Gaussian distribution (Waugh and Hall, 2002) as follows:

$$211 \quad G(\Gamma, t) = \left(\frac{\Gamma^3}{4\pi\Delta^2 t^3} \right)^{1/2} \exp \left[\frac{-\Gamma(t-\Gamma)^2}{4\Delta^2 t} \right], \quad (4)$$

212 where Δ denotes the width of the age spectrum. This function is known to be the Green's function of one-dimensional
 213 advective diffusion differential equation (Hall and Plumb, 1994). This function will be calculated by assuming the spectral
 214 width (Δ) and mean age (Γ). The mean age is determined by successively calculating the convolutions of equation (3)
 215 while varying the value of Γ and comparing $x(\Gamma, t)$ with the observed mole fractions. However, Δ is still unknown. Δ
 216 represents the effect of mixing process in atmospheric transport, and it is expected that the larger the mean age, the greater
 217 the effect of mixing and the Δ will be. Therefore, Δ is assumed to be given by the relationship $\Delta^2/\Gamma = \text{constant}$ (years).
 218 This value, called the ratio of moments, is suggested by Hall and Plumb (1994) from the results of a stratospheric AGCM.
 219 A ratio of moments of 0.7 years has been widely used in previous studies (e.g. Engel et al. 2002). However, recent progress
 220 in studies of age spectra and the ratio of moments has shown that the ratio of moments is currently not well constrained
 221 by either models or observations (Garny et al., 2024b). Fritsch et al. (2020) have reported that the mean age calculated
 222 from a virtual tracer with a linear trend using a numerical model is in good agreement with observed values when the
 223 ratio of moments value of 1.25 is assumed. We assumed the ratio of moments to be 1.25 years, a value reported by Fritsch
 224 et al. (2020). The CO₂ mole fraction was corrected for CH₄ oxidation and gravitational separation prior to the age
 225 calculation (Sugawara et al., 2025). The correction of the CO₂ mole fraction for gravitational separation is non-negligible
 226 and can be estimated by $C \times (m-m_{\text{air}}) \times \langle \delta_G \rangle$, where C is CO₂ mole fraction, m and m_{air} are the respective mass numbers of
 227 the molecule and air, $\langle \delta_G \rangle$ is the average gravitational separation (Ishidoya et al., 2006; Sugawara et al., 2025). The
 228 maximum depression of the CO₂ mole fraction due to the gravitational separation amounts to about 0.4 $\mu\text{mol mol}^{-1}$ at the
 229 altitudes over 30 km, assuming $C = 400 \mu\text{mol mol}^{-1}$ and $\langle \delta_G \rangle = -60$ per meg. The tropospheric reference records of CO₂
 230 and SF₆ mole fractions were prepared by using data from the automatic air sampling equipment used in the
 231 Comprehensive Observation Network for Trace gases by Airliner program (Machida et al., 2008; Sawa et al., 2008;
 232 Matsueda et al., 2015). Measurements of CO₂ mole fraction at altitudes 29 and 31 km in 2020 are not available due to

233 water contamination into sample air. The overall uncertainties of the mean ages derived from the CO₂ and SF₆ mole
234 fractions were estimated to be 0.7 and 0.8 years, respectively (Umezawa et al., 2025).

235 **3 Results and Discussion**

236 **3.1 Vertical profiles of noble gases**

237 Figure 2 shows the vertical profiles of the isotopic and elemental ratios of the noble gases, the $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$ and
238 $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$, and the CO₂- and SF₆-ages observed in the stratosphere over Japan on 4 June 2007 and 25 July 2020. It
239 should be noted that the isotopic and elemental ratios of noble gases measured at the NIPR were expressed as the values
240 relative to the ground surface air at Tachikawa, as described in Section 2.2. However, the $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$,
241 $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$, and $\delta(^{40}\text{Ar}/^{36}\text{Ar})$ measured at AIST were expressed relative to the values observed in the lowest layer of the
242 balloon observations. Although there are very few observations of the isotopic and elemental ratios of atmospheric major
243 components in the upper troposphere, aircraft observations have reported that there is no significant vertical gradient of
244 $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$ and $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$ from the surface to near the tropopause (Ishidoya et al., 2008a). On the other hand, Bent
245 (2014) observed $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$ in air samples obtained by the HIAPER Pole-to-Pole Observations (HIPPO) project and
246 reported a large vertical gradient in troposphere. However, such vertical gradient could not be explained by a 1-D
247 atmospheric diffusion model, and it was unclear whether it is either natural or artificial. As will be discussed later, our
248 results of 2-D model also show very small differences between the surface and the upper troposphere. Because the air
249 samples at the lowest layer were collected below the tropopause in our balloon observations, the differences of the isotopic
250 and elemental ratios between the ground surface and tropopause should be negligibly small. It is clearly apparent in this
251 figure that the isotopic and elemental ratios decreased with increasing altitude. The exception was the $\delta(^{22}\text{Ne}/^{40}\text{Ar})$ ratio,
252 which increased with increasing altitude because the difference of the masses of ²²Ne and ⁴⁰Ar was negative (-18 kg kmol^{-1})
253 for this elemental ratio. Previous studies have reported that $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$, $\delta(^{40}\text{Ar}/^{36}\text{Ar})$, and
254 $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$ decrease with increasing altitude because of gravitational separation (e.g., Ishidoya et al., 2013). Similar
255 vertical profiles have also been observed for other isotopic and elemental ratios of noble gases in the stratosphere.
256 Gravitational separation in the stratosphere, as revealed by observations of isotopic and elemental ratios of major
257 atmospheric components, indicated that the larger the difference of mass numbers, the greater the separation (Ishidoya et
258 al., 2013). The isotopic ratios of Ar, Kr, and Xe as well as the elemental ratios of $\delta(^{84}\text{Kr}/^{40}\text{Ar})$ and $\delta(^{132}\text{Xe}/^{40}\text{Ar})$ observed
259 in this study showed similar dependencies on mass number differences in the vertical profiles. For example, the mass
260 number differences of the Kr isotopic ratios— $\delta(^{86}\text{Kr}/^{82}\text{Kr})$, $\delta(^{86}\text{Kr}/^{83}\text{Kr})$, and $\delta(^{86}\text{Kr}/^{84}\text{Kr})$ —were 4, 3, and 2 kg kmol^{-1} ,
261 respectively, and the observed decreases with altitude were roughly proportional to these values. Because the uncertainties
262 in the analysis of Xe isotopic ratios— $\delta(^{132}\text{Xe}/^{129}\text{Xe})$, $\delta(^{136}\text{Xe}/^{129}\text{Xe})$, and $\delta(^{136}\text{Xe}/^{132}\text{Xe})$ —were much larger compared
263 to their vertical changes (Fig. 2c), their vertical gradients were not very significant. However, the larger the mass number
264 difference, the larger the decreasing with altitude, and a mass-dependent relationship similar to that observed for Ar and
265 Kr isotopic ratios was barely observed. The mass number differences of the elemental ratios $\delta(^{22}\text{Ne}/^{40}\text{Ar})$, $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$,
266 $\delta(^{84}\text{Kr}/^{40}\text{Ar})$, and $\delta(^{132}\text{Xe}/^{40}\text{Ar})$ were larger than those of the isotopic ratios, and the magnitudes of fractionation in the

mid-stratosphere were therefore significantly large. Among the elemental ratios, $\delta(^{132}\text{Xe}/^{40}\text{Ar})$ had the largest mass number difference (92 kg kmol⁻¹), and the fractionation was about -2000 per meg at altitudes above 30 km. In contrast, the absolute value of the mass number difference for $\delta(^{22}\text{Ne}/^{40}\text{Ar})$ was only 18 kg kmol⁻¹, which is much smaller than that of $\delta(^{84}\text{Kr}/^{40}\text{Ar})$ or $\delta(^{132}\text{Xe}/^{40}\text{Ar})$, but the fractionation was quite large, although the sign of the slope was positive.

As seen in Figure 2 and 3, there are irregular fluctuations of the isotopic and elemental ratios in the vertical distributions and some of them occur synchronously within the same gas species. Ar isotopic ratios, $\delta(^{40}\text{Ar}/^{36}\text{Ar})$, $\delta(^{40}\text{Ar}/^{38}\text{Ar})$ and $\delta(^{38}\text{Ar}/^{36}\text{Ar})$ observed in 2007 showed irregularly low values at altitude of 21 km. Kr isotopic ratios observed also showed similar variations at altitude of 26 km in 2007. Xe isotopic ratios below 21 km also showed similar variations, although their statistical significance is low. Unfortunately, the cause of these irregular variations is not clear at present. Because the irregular variations are not common to all gas species, it is likely that there were factors that had different effects on the gas species. The causes are not necessarily natural, and the possibility of small fractionations during sample air pretreatments cannot be ruled out. This issue, along with irregular variations in the isotopic and elemental ratios of the atmospheric major components, remains to be solved in the future.

These results led us to an investigation of the effects of mass number differences. A previous study of the major atmospheric components has shown that the values normalized by mass number differences (i.e., $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta(^{34}\text{O}_2/^{32}\text{O}_2)/2$, $\delta(^{40}\text{Ar}/^{36}\text{Ar})/4$, and $\delta(^{40}\text{Ar}/^{28}\text{N}_2)/12$) show almost the same degree of fractionation (Ishidoya et al., 2013). The implication is that the separations of these components are almost directly proportional to their mass number differences. In order to investigate the mass dependencies for noble gases, we defined the value normalized by the mass number difference, $\delta_n(\text{X}/\text{Y})$, as follows:

$$\delta_n(\text{X}/\text{Y}) = \frac{\delta(\text{X}/\text{Y})}{\Delta m_{\text{X},\text{Y}}} . \quad (5)$$

Hereafter, X and Y represent molecules associated with the observed ratio. The mass number difference between molecules X and Y is $\Delta m_{\text{X},\text{Y}}$. Figure 3 shows the vertical profiles of $\delta_n(\text{X}/\text{Y})$. It is apparent from Fig. 3 that the separations of $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$ ($= \delta(^{29}\text{N}_2/^{28}\text{N}_2)$) and $\delta_n(^{34}\text{O}_2/^{32}\text{O}_2)$ are large, followed by the isotopic ratios of Ar, Kr, and Xe in decreasing order. The average values of $\delta_n(\text{X}/\text{Y})$ at altitudes above 30 km are summarized in Table 1. The average values of $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta_n(^{34}\text{O}_2/^{32}\text{O}_2)$, $\delta_n(^{40}\text{Ar}/^{28}\text{N}_2)$, and $\delta_n(^{40}\text{Ar}/^{36}\text{Ar})$ measured by AIST were -54 ± 12 , -52 ± 9 , -63 ± 18 , and -48 ± 6 per meg, respectively, which are close to the values of gravitational separation reported by Ishidoya et al. (2013). However, the average values of $\delta_n(^{40}\text{Ar}/^{36}\text{Ar})$, $\delta_n(^{40}\text{Ar}/^{38}\text{Ar})$, and $\delta_n(^{38}\text{Ar}/^{36}\text{Ar})$ measured by the NIPR were -39 ± 9 , -38 ± 9 , and -40 ± 11 per meg, respectively, and those of $\delta_n(^{86}\text{Kr}/^{82}\text{Kr})$, $\delta_n(^{86}\text{Kr}/^{83}\text{Kr})$, and $\delta_n(^{86}\text{Kr}/^{84}\text{Kr})$ were -23 ± 1 , -23 ± 4 , and -24 ± 5 per meg, respectively. It is apparent from these results that the fractionations normalized by mass number differences are almost the same for each gas species and that the magnitudes are smaller for Kr than for Ar. Furthermore, the average values of $\delta_n(^{132}\text{Xe}/^{129}\text{Xe})$, $\delta_n(^{136}\text{Xe}/^{129}\text{Xe})$, and $\delta_n(^{136}\text{Xe}/^{132}\text{Xe})$ were -16 ± 4 , -14 ± 5 , and -18 ± 5 per meg, respectively. Their fractionations were even smaller than those of Kr. The average values of the elemental ratios $\delta_n(^{84}\text{Kr}/^{40}\text{Ar})$, $\delta_n(^{132}\text{Xe}/^{40}\text{Ar})$, and $\delta_n(^{22}\text{Ne}/^{40}\text{Ar})$ were -27 ± 4 , -21 ± 5 , and -80 ± 56 per meg, respectively. The average

300 values of $\delta_n(^{84}\text{Kr}/^{40}\text{Ar})$ and $\delta_n(^{132}\text{Xe}/^{40}\text{Ar})$ were intermediate between those of the isotopes of Kr and Ar and the isotopes
301 of Xe and Ar, respectively. These results indicated that mass-independent fractionations occurred in noble gases and that
302 the deviations from the values for $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$ increased with increasing molecular mass.

303 One of the noteworthy results was that there were differences between the vertical profiles observed during 2007 and
304 2020. In particular, the differences were significant for the isotopic ratios of O₂, N₂, and Ar as well as for the elemental
305 ratios of $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$, $\delta(^{84}\text{Kr}/^{40}\text{Ar})$, and $\delta(^{132}\text{Xe}/^{40}\text{Ar})$. In all cases, the fractionations in the mid-stratosphere were greater
306 in 2020 than in 2007. However, no clear difference was apparent in the Kr isotopic ratios. There was also a difference of
307 the CO₂ age between 2007 and 2020; the age in 2020 was larger. A previous study of gravitational separations has shown
308 that there is a positive correlation between the CO₂ age and the strength of gravitational separations in the mid-stratosphere
309 over Japan (Ishidoya et al., 2013). The implication is that gravitational separations may have been stronger in 2020 than
310 in 2007. However, there was no clear difference of SF₆ ages between 2007 and 2020. It has been pointed out that a
311 chemical sink for SF₆ in the mesosphere can lead to an overestimation of SF₆ age in the mid-stratosphere (e.g., Stiller et
312 al., 2012; Ray et al., 2017; Sugawara et al., 2018; Leedham Elvidge et al., 2018; Garny et al., 2024a). Because the SF₆
313 age estimated in this study was not corrected for the effect of mesospheric loss, it may have been overestimated. Such an
314 overestimation might explain the difference between the CO₂ age and SF₆ age in 2007. Future observations may lead to
315 a better understanding of the year-to-year variations of noble gases and the mean age of air.

316 3.2 Kinetic fractionations

317 Studies of fractionations of noble gases have been conducted for firn air on the surface of polar ice sheets and for bubble
318 air in ice core (Severinghaus et al., 2003; Severinghaus and Battle, 2006; Kawamura et al., 2013; Birner et al., 2018;
319 Buizert et al., 2023). Because molecular diffusion is dominant in firn air, unlike the free atmosphere, the deeper the air in
320 the firn, the more fractionations occur due to gravitational separation. Firn air that has reached equilibrium through
321 gravitational separation exhibits mass-dependent fractionation. However, thermal disturbances near the surface cause
322 thermal diffusion, and fluctuations of pressure and wind speed at the ground surface cause eddy diffusion. The result is
323 fractionations that are not governed simply by gravitational separation. In particular, Kawamura et al. (2013) were the
324 first to report that the kinetic fractionations of Kr and Xe isotopic ratios occur by convective mixing in a firn layer because
325 of the competition between eddy and molecular diffusion and the large differences between the molecular diffusivities of
326 Kr and Xe versus those of N₂ or Ar. That study was further expanded to consider use of excess-⁸⁶Kr as a quantitative
327 measure of the degree of gravitational disequilibrium in the firn layer (Severinghaus, 2016; Birner et al., 2018; Buizert
328 and Buizert et al., 2023). This approach in studies of firn air is expected to be of great help in interpreting the fractionations
329 of noble gases in the stratosphere discovered in the present study.

330 Advection and eddy diffusion are predominant in the atmosphere, unlike firn air, and therefore stratospheric air
331 is essentially in a state of gravitational disequilibrium with respect to molecular diffusions. The implications of this fact
332 can be applied to the gravitational separation of the major components of the atmosphere, which is quite different from
333 the fractionations determined by the gravitational equilibrium in firn air. Fractionation in gravitational equilibrium (δ_{GE})

334 is given by Eq. (6):

335
$$\delta_{GE} = \exp\left(-\frac{\Delta m g z}{RT}\right) - 1, \quad (6)$$

336 where Δm , g , R , and T denote the mass number difference, gravitational acceleration, the gas constant, and temperature
337 (K), respectively. The variable z is the altitude (m) above the ground, but it can also be the depth in a firn if it is negative.
338 Because the lowermost z value is about -100 m for firn air, $\frac{\Delta m g z}{RT}$ is less than 10^{-3} . Equation (6) can therefore be
339 approximated by Eq. (7):

340
$$\delta_{GE} \approx -\frac{\Delta m g z}{RT}. \quad (7)$$

341 It is clear from Eq. (7) that gravitational equilibrium is dependent on mass in firn air. For example, the value of δ_{GE} is
342 about -4.7 per meg m^{-1} at $\Delta m = 1$ and $T = 250$ K. This value is typical of gravitational separations in a firn and is
343 equivalent to 0.47 per mil enrichment at $z = -100$ m relative to the surface of a firn. In the stratosphere, typical
344 gravitational separation at an altitude of about 35 km in the mid-latitudes, which is approximately 20 km higher than the
345 height of the tropopause, is about 60 per meg (Ishidoya et al., 2013; Sugawara et al., 2018). The vertical gradient for this
346 fractionation is about -0.003 per meg m^{-1} . The magnitude of gravitational separation in the stratosphere is therefore
347 roughly $1/1900$ – $1/1700$ of the degree of gravitational equilibrium at temperatures of 210 – 230 K. The implication is that
348 the major difference between firn air and the stratosphere is the degree of gravitational disequilibrium. In this almost
349 overwhelming state of disequilibrium, N_2 , O_2 , and Ar are undergoing mass-dependent fractionations in the stratosphere,
350 probably because the diffusivities of these molecules are roughly the same. However, the diffusivities of Ne , Kr , and Xe
351 are significantly different from those of the major components of the atmosphere, and kinetic fractionation is therefore
352 thought to be prominent in the stratosphere.

353 In previous studies of the isotopic and elemental ratios of the major components of the atmosphere, $\langle\delta_G\rangle$ has been
354 defined to be an average gravitational separation normalized by the difference of mass numbers and has been
355 evaluated as follows:

356
$$\langle\delta_G\rangle = \frac{1}{3} \left[\delta_n\left(\frac{^{29}N_2}{^{28}N_2}\right) + \delta_n\left(\frac{^{34}O_2}{^{32}O_2}\right) + \delta_n\left(\frac{^{40}Ar}{^{36}Ar}\right) \right]. \quad (8)$$

357 In Eq. (8), δ values are always taken to be zero in the troposphere and are expressed as deviations from zero. Equation
358 (8) is based on the observation that the decreases of the three isotopic and elemental ratios with altitude are dominated by
359 mass-dependent processes. It has also been confirmed by numerical models that gravitational separations form a mass-
360 dependent vertical profile for these three ratios (Ishidoya et al., 2013). The gravitational separation can be expressed
361 generally using $\langle\delta_G\rangle$ as follows:

362
$$\delta_G(X/Y) = \Delta m_{X,Y} \times \langle\delta_G\rangle. \quad (9)$$

363 However, $\delta(X/Y)$ values for the heavy noble gases are clearly smaller than the mass-dependent value of $\delta_G(X/Y)$, as

364 described above. We considered the similarity of fractionation to the gravitational disequilibrium in firn air and introduced
 365 a quantity that represented the magnitude of the kinetic fractionations in the stratosphere. The values of $r(X/Y)$ and
 366 $\psi(X/Y)$ corresponding to the isotopic or elemental ratio of $\delta(X/Y)$ were defined as follows:

$$367 \quad r(X/Y) = \frac{\delta_n(X/Y)}{\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)}, \quad (10)$$

$$368 \quad \psi(X/Y) = r(X/Y) - 1. \quad (11)$$

369 The value of $r(X/Y)$ is the ratio of $\delta_n(X/Y)$ relative to $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$. If the variation of $\delta(X/Y)$ were due to only
 370 gravitational separation, then $r(X/Y)$ and $\psi(X/Y)$ would be expected to equal 1 and zero, respectively. Figure 4 shows the
 371 relationship between $\delta_n(X/Y)$ and $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$. The values of $r(X/Y)$ were determined by fitting a linear function to the
 372 relationship between the two values. Values of $\psi(X/Y)$ are quantities that generalize the concept of excess- ^{86}Kr ($^{86}\text{Kr}_{\text{XS15}}$)
 373 used in the ice core analysis by Buizert et al. (2023) to all other isotopic and elemental ratios. For the heavy noble gases,
 374 the process of air mixing due to eddy diffusion produces gravitational disequilibrium, and the values of $\psi(X/Y)$ are always
 375 negative. Table 1 summarizes the values of $r(X/Y)$ and $\psi(X/Y)$. The values of $r(X/Y)$ were roughly close to 1.0 for the
 376 $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$, $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$, and Ar isotopic ratios, but they were clearly smaller than 1.0 for the heavy noble gases. For
 377 example, if we compare $\delta(^{40}\text{Ar}/^{36}\text{Ar})$, $\delta(^{86}\text{Kr}/^{82}\text{Kr})$, and $\delta(^{136}\text{Xe}/^{132}\text{Xe})$, which all have mass number differences of 4 kg
 378 kmol^{-1} , the heavier the noble gas, the lower $r(X/Y)$. As shown in Table 1, the $r(X/Y)$ values decreased significantly in
 379 the order Ar, Kr, and Xe; the lowest values were 0.24–0.38 per meg (per meg) $^{-1}$ for the Xe isotopic ratios. These facts
 380 suggested that the kinetic fractionations are not all the same and depend on the element.

381 If the anomalously low $r(X/Y)$ and $\psi(X/Y)$ values of the heavy noble gases were due to kinetic fractionations,
 382 differences of molecular diffusivities would likely be important. We therefore compared the diffusivities of all molecules
 383 involved in this study and investigated the relationships between the observed fractionations and diffusivities. According
 384 to Reid et al. (1987), the diffusivity of molecule X in air is given by Eq. (12):

$$385 \quad D_{X,\text{air}} = 1.43 \times 10^{-4} \frac{T^{1.75}}{p} \frac{1}{\phi_{X,\text{air}}} \quad (\text{m}^2 \text{s}^{-1}), \quad (12)$$

386 where T and p denote temperature (K) and pressure (hPa), respectively. The variable $\phi_{X,\text{air}}$ is independent of temperature
 387 and pressure and is given by Eq. (13):

$$388 \quad \phi_{X,\text{air}} = \sqrt{m_{X,\text{air}}} \left(\sqrt[3]{\sigma_X} + \sqrt[3]{\sigma_{\text{air}}} \right)^2, \quad (13)$$

389 where σ_X and σ_{air} are the diffusion volumes of a molecule X and of air, respectively. The diffusion volume parameter was
 390 originally introduced by Fuller et al. (1966, 1969) for a semi-empirical method to estimate diffusivity. We used values of
 391 atomic diffusion volume parameters listed in Table 11-1 of Reid et al. (1987). The variable $m_{X,\text{air}}$ is the harmonic mean of
 392 mass numbers for molecule X and air and is given by Eq. (14):

393 $m_{X,air} = 2 \left(\frac{1}{m_X} + \frac{1}{m_{air}} \right)^{-1}$. (14)

394 Table 2 summarizes these values along with the ratios of diffusivities relative to $^{28}\text{N}_2$. In Table 2, the value of $D_{X,air}$ is an
 395 example at 1000 hPa and 273 K, but the ratio $D_{X,air}/D_{28\text{N}_2,air}$ is independent of temperature and pressure. The lightest and
 396 heaviest molecules, ^{22}Ne and ^{136}Xe , have the largest and smallest diffusivity ratios of 1.495 and 0.634, respectively. The
 397 diffusivity therefore varies greatly as a function of the mass of the molecule, and that dependence is an important cause
 398 of kinetic fractionation. Although molecular diffusivities are dependent on molecular masses, the relationship between
 399 them is not approximated by a simple function. Furthermore, the value of $\delta(X/Y)$ is influenced by the individual molecular
 400 diffusivities of X and Y in air. To understand the relationship between kinetic fractionations and molecular diffusivities,
 401 the diffusivities of both X and Y must therefore be considered. As shown in Table 1, the values of $\psi(^{84}\text{Kr}/^{40}\text{Ar})$ and
 402 $\psi(^{132}\text{Xe}/^{40}\text{Ar})$ are intermediate between the values of ψ for Ar and Kr and for Ar and Xe, respectively. We therefore
 403 transformed Eq. (13) and introduced $\phi_{X,Y}$ corresponding to $\delta(X/Y)$ as follows:

404 $\phi_{X,Y} = \sqrt{m_{X,Y}} (\sqrt[3]{\sigma_X} + \sqrt[3]{\sigma_Y})^2$, (15)

405 where $m_{X,Y}$ is the harmonic mean of the mass numbers for molecules X and Y. The diffusivity factor, $\mu_{X,Y}$, is then defined
 406 as the ratio of $\phi_{29\text{N}_2,28\text{N}_2}$ to $\phi_{X,Y}$ as follows:

407 $\mu_{X,Y} = \frac{\phi_{29\text{N}_2,28\text{N}_2}}{\phi_{X,Y}}$. (16)

408 This diffusivity factor equals the ratio $D_{X,Y}/D_{29\text{N}_2,28\text{N}_2}$, which is independent of temperature and pressure. Table 1 shows
 409 the values of $m_{X,Y}$ and $\mu_{X,Y}$. Figure 5a shows the correlation between $\mu_{X,Y}$ and the observed $r(X/Y)$. It is apparent from
 410 this figure that $r(X/Y)$ is roughly proportional to $\mu_{X,Y}$. The implication is that the kinetic fractionations of noble gases in
 411 the stratosphere can be explained by the differences of their molecular diffusivities.

412 Figure 6 is a schematic representation that explains the vertical distribution of the gravitational separations and kinetic
 413 fractionations in firn air and the stratosphere. As mentioned above, the results from firn air have been extremely useful in
 414 interpreting the kinetic fractionation of the stratosphere, and the differences between firn air and the stratosphere have
 415 also been clarified by this study. In firn air, the environment is basically close to gravitational equilibrium, and the
 416 magnitude of kinetic fractionation is relatively small. As shown in Fig. 6, the value of $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$ at the bottom of the
 417 firn layer varies as a function of the thickness of the diffusive zone, but the typical value is $\sim 0.4\text{‰}$ (e.g., Landais et al.,
 418 2006). In contrast, because the zone in which kinetic fractionation occurs is a narrow layer between the well-mixed and
 419 diffusive zones, the difference between $\delta_n(X/Y)$ and $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$ is roughly -20 and -30 per meg for the Kr and Xe
 420 isotopic ratios, respectively, at the bottom of a firn (Kawamura et al., 2013). If we calculate the excess value from these
 421 values, then (for example) $\psi(^{86}\text{Kr}/^{82}\text{Kr})$ is approximately -50 per meg ‰^{-1} . Buizert et al. (2023) have reported a
 422 $\psi(^{86}\text{Kr}/^{82}\text{Kr})$ value for the last 25 kilo-years from an analysis of an ice core from the West Antarctic Ice Sheet Divide and
 423 have used it as a proxy for dispersive mixing due to barometric pumping in firn air. They have reported $\psi(^{86}\text{Kr}/^{82}\text{Kr})$

424 values that range from 0 to -60 per meg ‰^{-1} . However, the fractionations in the stratosphere observed in this study were
 425 -60 and -25 per meg for $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$ and $\delta_n(^{86}\text{Kr}/^{82}\text{Kr})$, respectively, at an altitude of ~ 35 km (Fig. 3). The difference,
 426 35 per meg, is roughly close to the value at the bottom of the firn, but it is comparable to the fractionation of $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$
 427 in the stratosphere. Therefore, $\psi(^{86}\text{Kr}/^{82}\text{Kr})$ is about 0.6 per meg (per meg) $^{-1}$ ($= 600$ per meg ‰^{-1}). The implication is that
 428 the excess value is roughly tenfold those in firn air. The explanation is that, unlike firn air, the atmosphere is in a state of
 429 significant disequilibrium throughout all of its layers, and gravitational separation and kinetic fractionation have
 430 comparable effects on the fractionation of heavy noble gases.

431 As shown in Fig. 5a, the relationship between $r(X/Y)$ and $\mu_{X,Y}$ in some cases is nonlinear. The elemental ratios and
 432 the isotopic ratios of Ar tend to have smaller $r(X/Y)$ values than those predicted from a linear relationship between $r(X/Y)$
 433 and $\mu_{X,Y}$. The reason for the nonlinearity is unclear at this time, but one of the possible reasons is an effect of thermal
 434 diffusion. The effects of thermal diffusion in the stratosphere have not been studied and are not well understood for noble
 435 gases. It is presently considered difficult to clearly quantify the contribution of fractionation due to thermal diffusion in
 436 the stratosphere.

437 3.3 Two-dimensional model

438 We hypothesized that the vertical profiles of noble gases revealed in this study reflected the effects of not only
 439 gravitational separation but also kinetic fractionation due to differences of molecular diffusivities, as described above. To
 440 verify this hypothesis, we performed numerical simulations using a two-dimensional model of the middle atmosphere
 441 (SOCRATES) developed by the National Center for Atmospheric Research (Huang et al., 1998; Park et al., 1999;
 442 Khosravi et al., 2002). This model has previously been used to reproduce the gravitational separation of the atmospheric
 443 major components (Ishidoya et al., 2013; Sugawara et al., 2018). Only a brief description of the method is therefore given
 444 here. To reproduce fractionations of stratospheric noble gases, the flux associated with molecular diffusion must be
 445 calculated. The vertical component of the flux due to molecular diffusion for molecular species X is given by

$$446 F_{X,z} = -D_{X,\text{air}} \left\{ \frac{\partial n_X}{\partial z} + \frac{m_X g}{RT} n_X + (1 + \alpha_{TX}) \frac{\partial(\ln T)}{\partial z} n_X \right\}, \quad (17)$$

447 where n_X , m_X , and α_{TX} are the number density, molecular mass, and thermal diffusion factor of species X, respectively,
 448 and g , R , and T denote the acceleration of gravity, the gas constant, and temperature, respectively (Banks and Kockarts,
 449 1973). As described before, the process of thermal diffusion in the stratosphere is presently unclear and was ignored in
 450 this study. Because noble gases were not included in the original SOCRATES model, we updated it to perform calculations
 451 for all molecules shown in Table 2. The mole fraction was calculated for each molecule, and then the isotopic and
 452 elemental ratios $\delta(X/Y)$ were calculated offline. Equation (12) was used to calculate the molecular diffusivity, $D_{X,\text{air}}$. All
 453 $\delta(X/Y)$ at the ground surface were set to zero as a boundary condition. However, this boundary condition was not used
 454 when we considered tropospheric enrichment (see Section 3.4). In addition to the noble gases, we added a virtual clock
 455 tracer to the model. The tracer increases in proportion to elapsed time at the ground surface and was used to calculate the
 456 mean age of air. A previous study has shown that the intensity of Brewer–Dobson circulation in SOCRATES is too large

457 to reproduce the mean age of stratospheric air (Sugawara et al., 2018). We therefore arbitrarily reduced the mass stream
458 function of the residual mean meridional circulation (hereafter, RMC) to calculate a realistic mean age. This change also
459 improved the reproduction of gravitational separation. We used a 40-year spin-up calculation to achieve steady state
460 fractionations and then ran the simulation for another 20 years (“control run”). The simulation time step was 5 days. The
461 monthly average values in the last 5 years were compared with observations. Although the observations were carried out
462 in different months (i.e., June 2007 and July 2020), the differences of the monthly averages simulated for June and July
463 were small. We therefore simply averaged the δ values simulated for those months.

464 The average meridional distributions simulated by SOCRATES are shown in Fig. 7 for $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta(^{40}\text{Ar}/^{36}\text{Ar})$,
465 $\delta(^{86}\text{Kr}/^{82}\text{Kr})$, and $\delta(^{132}\text{Xe}/^{129}\text{Xe})$ and in Fig. 8 for $\delta(^{84}\text{Kr}/^{40}\text{Ar})$, $\delta(^{132}\text{Xe}/^{40}\text{Ar})$, and $\delta(^{22}\text{Ne}/^{40}\text{Ar})$ together with the results
466 for the mean age of air (Fig. 8d). The simulated vertical profiles at 40°N were shown in Figure 2 and 3. Figure 4 shows
467 the relationships between the $\delta_n(\text{X}/\text{Y})$ values and $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$ simulated at 40°N. It is apparent from these figures that
468 the simulated fractionations closely reproduced the observed results in 2007, but the simulations slightly underestimated
469 the observed results in 2020. The most important point was that the model simulations basically reproduced smaller and
470 larger $\delta_n(\text{X}/\text{Y})$ values of the heavy (Kr and Xe) and light (Ne) noble gases, respectively, compared with the $\delta_n(^{29}\text{N}_2/^{28}\text{N}_2)$
471 (Fig. 4). Both the mass-dependent gravitational separations and the kinetic fractionations were therefore reproduced by
472 the model. Figure 5b shows the relationship between $r(\text{X}/\text{Y})$ and the diffusivity factor $\mu_{\text{X},\text{Y}}$ reproduced by the model. It
473 is apparent in this figure that the values of $r(\text{X}/\text{Y})$ simulated for the isotopic and elemental ratios of major atmospheric
474 components, $\delta(^{84}\text{Kr}/^{40}\text{Ar})$ and $\delta(^{132}\text{Xe}/^{40}\text{Ar})$, were related almost linearly to $\mu_{\text{X},\text{Y}}$. However, the fact that the values of
475 $r(\text{X}/\text{Y})$ simulated for the isotopic ratios of Kr and Xe were closer to 1.0 than the observed results meant that the kinetic
476 fractionations were underestimated for the isotopic ratios of heavy molecules. The reason for these underestimations of
477 kinetic fractionation is presently unclear. Only the mean circulation was arbitrarily reduced in these simulations, and the
478 eddy diffusion coefficient was not changed. Such adjustments may have been unrealistic and contributed to the
479 underestimation of kinetic fractionation. The effects of eddy diffusions on kinetic fractionations are discussed in Section
480 3.5.

481 To investigate the kinetic fractionation, the relative contributions of molecular and eddy diffusion are important. In an
482 environment dominated by molecular diffusion alone, gravitational separation according to the mass number difference
483 of molecules occurs, whereas in an environment dominated by eddy diffusion alone, separation according to molecular
484 species is not expected to occur. The Péclet number (Pe) is a dimensionless number defined as the ratio of the transport
485 rates of advection and diffusion. It is known that kinetic fractionations occur in firn air under conditions where molecular
486 and eddy diffusivities are in competition (Kawamura et al., 2013) and the Pe is approximately 1. Such conditions in
487 Earth’s atmosphere appear only in the upper atmosphere at altitudes greater than 100 km. It is therefore likely that large
488 kinetic fractionations occur in the upper atmosphere at altitudes above 100 km. However, the predominance of advection
489 and eddy diffusion in the troposphere and stratosphere means that the Pe must be much larger than 1. As is apparent from
490 Eq. (17), the flux associated with molecular diffusion in the atmosphere is usually considered only in the vertical direction.
491 However, three-dimensional advection and eddy diffusion are essential in atmospheric transport processes. It is therefore
492 difficult to define Pe in the free atmosphere. Given that fractionations occur mainly in the vertical direction and that the

493 similarity with the Pe in firn air (Buizert et al., 2023) was considered, we approximated the Pe of molecular species X in
494 the atmosphere as follows:

495
$$Pe_X = \frac{|w|H + K_{zz}}{D_X}, \quad (18)$$

496 where w, H, and K_{zz} denote the vertical component of the RMC, atmospheric scale height ($=RT/m_{air}g$), and vertical eddy
497 diffusion coefficient, respectively. We decomposed Pe_X into its advection and eddy diffusion components ($Pe_{X,w} = \frac{|w|H}{D_X}$
498 and $Pe_{X,K} = \frac{K_{zz}}{D_X}$) and simulated them for $^{28}\text{N}_2$, as shown in Fig. 9. Because atmospheric pressure decreases exponentially
499 with increasing altitude and molecular diffusivity is inversely proportional to atmospheric pressure, both components of
500 the Pe values are $O(10^2)$ – $O(10^3)$ in the mid-stratosphere. They decrease with increasing altitude and are $O(10^{-1})$ – $O(10^0)$
501 at altitudes of ~ 100 km. The high Pe numbers in the mid-stratosphere compared to firn air seem to contradict the fact that
502 kinetic fractionations are observable in the stratosphere. This apparent contradiction may be related to the difference in
503 the vertical ranges of both observations: the range is about $O(10^1$ – $10^2)$ m in the firn but about $O(10^4)$ m in the stratosphere.
504 Small kinetic fractionations may therefore be observed at high altitudes up to about 35 km. These results imply that
505 observing kinetic fractionation in the lower stratosphere may be difficult because the Pe is large, and the vertical range is
506 narrow.

507 Although the Pe is usually defined as a positive value, the actual vertical component of the RMC is upwelling ($w > 0$)
508 inside the low-latitude “tropical pipe” (e.g., Neu and Plumb, 1999) and downwelling ($w < 0$) at higher latitudes. The
509 relationship between $Pe_{X,w}$ and kinetic fractionation is therefore expected to differ between the tropics and higher latitudes.
510 In this relationship, the magnitude of gravitational separation in the stratosphere is much smaller above the equatorial
511 region than in the mid-latitudes (Sugawara et al., 2018). Unfortunately, there are no observations of noble gases above
512 the equator, but our model calculations shown in Figs. 7 and 8 predict that the $\psi(X/Y)$ values of heavy noble gases are
513 slightly lower in the equatorial mid-stratosphere than in the mid-latitude mid-stratosphere. The implication is that kinetic
514 fractionations vary with latitude in the stratosphere.

515 Although our model results tended to underestimate the kinetic fractionations of heavy noble gases, the observed
516 results that their fractionations were smaller than those expected from mass-dependent gravitational separation were
517 reproduced well in our simulation, in which large differences of molecular diffusivities were essential for the kinetic
518 fractionation of noble gases in the stratosphere. In the following sections, we use the model to further extend our
519 investigations to possible tropospheric enrichments driven by stratospheric fractionations (Section 3.4) and to the
520 sensitivity of the fractionation of noble gases to stratospheric transport processes (Section 3.5).

521 3.4 Tropospheric enrichments and possible variations of tropospheric noble gases

522 The isotopic and elemental ratios of noble gases in the troposphere were set to zero in this study because we expected
523 that their variations in the troposphere would be negligibly small. However, if we assume that the total amount of noble
524 gases in the atmosphere is conserved, the fact that the $\delta(X/Y)$ of noble gases decreases monotonically with altitude
525 (increases for ^{22}Ne) due to fractionation in the stratosphere suggests that the noble gases are enriched (diluted for ^{22}Ne)

526 at the ground surface. In addition, a change over a long period of time of atmospheric transport processes such as the
 527 Brewer–Dobson circulation in the stratosphere would change the fractionations of noble gases, not only in the stratosphere
 528 but also in the troposphere. This idea has been used to interpret long-term variations of $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$ in the troposphere.
 529 That interpretation has shown that changes of the Brewer–Dobson circulation can affect the long-term trend of
 530 $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$ near the ground surface (Ishidoya et al., 2021). In this study, the same approach was applied to the isotopic
 531 and elemental ratios of all observed noble gases, and model simulations were performed for several scenarios. We
 532 expressed the total amount of molecular species X in the atmosphere as $N(X)$. By replacing the reference values in Eqs.
 533 (1) and (2) with the ratio of N values, we newly defined $\delta_\Omega(X/Y)$ as follows:

$$534 \quad \delta_\Omega(X/Y) = \frac{[n(X)/n(Y)]_{sp}}{[N(X)/N(Y)]_{\square}} - 1. \quad (19)$$

535 If $\Delta m_{X,Y} > 0$, this value will be positive near the ground surface and negative at altitudes above the lower stratosphere. It
 536 is difficult to obtain the value of $\delta_\Omega(X/Y)$ from atmospheric observations, but it can be calculated using numerical models.
 537 For example, Fig. 10 shows the values of $\delta_\Omega(^{132}\text{Xe}/^{40}\text{Ar})$ calculated by SOCRATES. It is apparent from this figure that
 538 the enrichment near the surface is 132–138 per meg and that an isosurface where $\delta_\Omega(^{132}\text{Xe}/^{40}\text{Ar})$ equals zero exists near
 539 the lower stratosphere. It is also apparent that the altitude of the zero isosurface is higher near the equator and lower at
 540 high latitudes. This latitudinal dependence is due to Brewer–Dobson circulation. Because tropospheric air is well mixed,
 541 there is little dependence of $\delta_\Omega(^{132}\text{Xe}/^{40}\text{Ar})$ on altitude within the troposphere, but it decreases rapidly above the
 542 tropopause. The fact that the latitudinal difference at the ground surface is less than 8 per meg implies that it is difficult
 543 to detect latitudinal differences with the current observational precision. Figure 11 shows the vertical profiles of $\delta_\Omega(X/Y)$
 544 for various ratios at 40°N. Table 3 shows the annual mean values of $\delta_\Omega(X/Y)$ at the ground surface in the control run. The
 545 values of $\delta_\Omega(^{29}\text{N}_2/^{28}\text{N}_2)$ and $\delta_\Omega(^{40}\text{Ar}/^{28}\text{N}_2)$ at the ground surface were 2.4 and 28 per meg, respectively. The value
 546 normalized by the mass number difference for $\delta_\Omega(^{40}\text{Ar}/^{28}\text{N}_2)$ was therefore $28/12 = 2.3$ per meg. The enrichment was
 547 therefore almost directly proportional to the mass difference. In contrast, the normalized value of $\delta_\Omega(^{132}\text{Xe}/^{40}\text{Ar})$ at the
 548 ground surface was 1.44 per meg, which was clearly smaller than the $\delta_\Omega(^{29}\text{N}_2/^{28}\text{N}_2)$ of 2.4 per mg. This difference was
 549 due to the effect of kinetic fractionation in the upper air, and the corresponding $\psi(^{132}\text{Xe}/^{40}\text{Ar})$ value was -0.40 per meg
 550 (per meg) $^{-1}$. These results suggested that kinetic fractionation in the stratosphere influenced tropospheric fractionation,
 551 although its magnitude was much smaller in the troposphere than in the stratosphere.

552 We carried out additional simulations to investigate the possibility that the value of $\delta_\Omega(X/Y)$ at the ground surface
 553 changed with the change of stratospheric circulation. If the Brewer–Dobson circulation strengthened with time, the
 554 stratosphere–troposphere exchange would also be enhanced, and that enhancement would act to homogenize $\delta_\Omega(X/Y)$
 555 and simultaneously reduce the mean age of stratospheric air. Conversely, if the stratospheric circulation weakened, the
 556 vertical differences of $\delta_\Omega(X/Y)$ and the mean age would increase. We therefore performed model simulations in which
 557 we changed the RMC in SOCRATES using a method similar to the method applied by Ishidoya et al. (2021). Although
 558 many studies have been conducted on the mean age of stratospheric air and possible changes of transport processes,

559 whether the mean age in the mid-stratosphere is increasing or decreasing is unclear at present (e.g., Engel et al., 2009;
560 Garny et al., 2024b). For example, Diallo et al. (2012) have reported that the mean age was increasing at a rate of about
561 0.3 years decade⁻¹ in the mid-stratosphere during the period 1989–2010 based on the ERA-Interim reanalysis data.
562 However, Engel et al. (2017) have reported that there was no significant trend of the age of air observed by high-altitude
563 balloons during the period 1975–2016; the age increased very slightly at a rate of $+0.15 \pm 0.18$ years decade⁻¹, which was
564 supported by more recent result of CO₂-age observation (Sugawara et al., 2025). Based on these results, the RMC in the
565 model was gradually weakened during the 20-year period so that the mean age of air increased by 0.15 years decade⁻¹ at
566 an altitude of 35 km over the northern mid-latitudes (“weakened-RMC” scenario) to evaluate the sensitivities of the noble
567 gases to this change. The results are shown in Fig. 12a for the mean age and in Fig. 12b–f for $\delta_{\Omega}(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta_{\Omega}(^{40}\text{Ar}/^{28}\text{N}_2)$,
568 $\delta_{\Omega}(^{84}\text{Kr}/^{40}\text{Ar})$, $\delta_{\Omega}(^{132}\text{Xe}/^{40}\text{Ar})$, and $\delta_{\Omega}(^{22}\text{Ne}/^{40}\text{Ar})$ simulated in the mid-latitudes at the ground surface and an altitude of 35
569 km. The values of δ_{Ω} increased monotonically at the surface (decreased in the case of $\delta_{\Omega}(^{22}\text{Ne}/^{40}\text{Ar})$) accompanied by
570 seasonal cycles. In contrast to the ground surface, δ_{Ω} values decreased (increased in the case of $\delta_{\Omega}(^{22}\text{Ne}/^{40}\text{Ar})$) in the
571 stratosphere. There was hence an increase of the difference between the stratosphere and ground surface. Table 3
572 summarizes the rate of change calculated by fitting a linear function to each $\delta_{\Omega}(X/Y)$. The long-term rates of change
573 simulated at the ground surface were small for the $\delta_{\Omega}(X/Y)$ of the isotopes of Kr and Xe and for $\delta_{\Omega}(^{22}\text{Ne}/^{40}\text{Ar})$ compared
574 to the precisions of the observations. Such small changes would be difficult to detect at present. If the changes were
575 monitored over a long period of time and the measurements were adequately precise, detectability of trends would be
576 highest in the order $\delta_{\Omega}(^{40}\text{Ar}/^{28}\text{N}_2) > \delta_{\Omega}(^{40}\text{Ar}/^{36}\text{Ar}) > \delta_{\Omega}(^{34}\text{O}_2/^{32}\text{O}_2) > \delta_{\Omega}(^{84}\text{Kr}/^{40}\text{Ar})$. In fact, Ishidoya et al. (2021) have
577 estimated the effect of a change of stratospheric circulation on $\delta_{\Omega}(^{40}\text{Ar}/^{28}\text{N}_2)$ at the ground surface, and they have
578 suggested that it has a significant influence on estimates of ocean heat content based on long-term $\delta(^{40}\text{Ar}/^{28}\text{N}_2)$
579 observations. If the precision of measurements is improved and/or high-frequency observations are made for other noble
580 gases, it is likely that long-term trends will be detectable at the ground surface in future studies.

581 We have also conducted simulations of enhanced-RMC scenario so that the mean age of air decreased by 0.15 years
582 decade⁻¹ at an altitude of 35 km over the northern mid-latitudes. The resulting trends in δ_{Ω} at the ground surface and mid-
583 stratosphere were the opposite of those of the weakened-RMC scenario, but their magnitudes were almost the same.
584 Similar results have been also shown in trends simulated for $\delta(\text{Ar}/\text{N}_2)$ by Ishidoya et al. (2021).

585 Recent studies have shown that the shallow and deep branches of the BDC show different trends, and it is important
586 to distinguish between them. Indeed, reanalysis data and 3-D model results have reported that the mean ages of air in the
587 shallow and deep branches change differently (e.g. Garny et al., 2024). However, it is difficult to fully discuss the
588 differences between the shallow and deep branches of the BDC using a 2-D model, this study simply examined the
589 sensitivities of noble gas fractionations at the ground surface to the change in entire stratosphere as a first approach. We
590 believe that the differences of changes between the shallow and deep branches of the BDC will be a future challenge,
591 such as modeling noble gases using a 3-D model.

592 Recently, Ishidoya et al. (2025) have reported long-term trends of tropospheric $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$ associated with the Dole–
593 Morita effect. They continuously measured atmospheric $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$ at Tsukuba, Japan, near the ground surface during
594 2013–2022 and found that the peak-to-peak amplitude of the average seasonal cycle was about 2 per meg and that there

595 was an increasing trend of $+2.2 \pm 1.4$ per meg decade $^{-1}$. The results of our simulations showed that the seasonal cycle
596 driven by fractionations in the upper atmosphere contributed 0.5 per meg to the peak-to-peak amplitude. However,
597 because the maximum of the simulated seasonal cycle was in late summer, the phase of the seasonal cycle was antiphase
598 to that observed by Ishidoya et al. (2025). The observed seasonal cycle of $\delta(^{34}\text{O}_2/^{32}\text{O}_2)$, which is driven by biological
599 processes, may therefore be slightly weakened by upper atmospheric fractionation. Furthermore, our results simulated
600 with the weakened-RMC scenario showed that the trend of $\delta\Omega(^{34}\text{O}_2/^{32}\text{O}_2)$ at the ground surface could be $+0.24$ per meg
601 decade $^{-1}$. This rate of change is approximately 1/10 of the result observed by Ishidoya et al. (2025), but it may not be
602 negligible if detailed consideration is given to the long-term changes of the Dole–Morita effect.

603 3.5 Sensitivity of kinetic fractionations to model dynamics

604 Because spatiotemporal variations of the age of stratospheric air are governed only by stratospheric transport processes,
605 a study of those variations is an effective way to diagnose the dynamics of the stratosphere (e.g., Waugh and Hall, 2002;
606 Garny et al., 2024b). Many studies have therefore been conducted to compare the results of observations of the age of the
607 stratosphere with the results of numerical models. Climate models have predicted a long-term decrease of the age of air
608 in the northern mid-latitudinal mid-stratosphere. However, long-term balloon observations have not revealed such a
609 decreasing trend. The latest developments in studies of the age of air have been detailed by Garny et al. (2024b). At
610 present, observations of the age of air are inconclusive, and climate models have also not been able to adequately
611 reproduce the age of air. One major problem has been that many current climate models tend to underestimate the age of
612 air. In model calculations, the mean age of air can be decomposed into a residual circulation transit time (RCTT) and a
613 term characterized as “aging by mixing”. The latter phenomenon is due to eddy mixing and recirculation, which Garny
614 et al. (2014) have argued is particularly important in the mid-latitude stratosphere. They have also suggested that the
615 strength of mixing is tightly coupled to the strength of the RMC. However, it is impossible to distinguish RCTT and
616 “aging by mixing” based on observations of age tracers alone. Gravitational separations and kinetic fractionations increase
617 with altitude and are similar to age of air in that respect, but they are thought to be physical quantities that are particularly
618 sensitive to vertical advection and mixing. This sensitivity reflects the fact that molecular diffusivities increase rapidly
619 with increasing altitude as atmospheric pressure decreases. It is therefore likely that the sensitivity of the fractionation of
620 noble gases differs from the sensitivity of the mean age of air to the changes of stratospheric transport processes and could
621 provide new constraints for numerical models in addition to the age of air.

622 In Section 3.4, we described the simulated results of noble gases in response to the scenario of a weakened RMC
623 (hereafter scenario A). In addition to this simulation, we performed a sensitivity test in which not only the RMC but also
624 the vertical and horizontal eddy diffusion coefficients, K_{zz} and K_{yy} , were gradually weakened by 0.5 % year $^{-1}$ for the
625 entire atmosphere (“weakened-RMC&K” scenario, hereafter scenario B). We also performed calculations in which only
626 K_{zz} was arbitrarily increased by a factor of 1.3 (“enhanced- K_{zz} scenario”, hereafter scenario C) because the Pe is directly
627 dependent on K_{zz} . It is therefore expected that the kinetic fractionations of noble gases will be significantly influenced by
628 a change of K_{zz} . Figure 13 shows the deviations of the mean age of air, $\delta_n(X/Y)$, as well as $\psi(X/Y)$ at an altitude of 35

629 km in the northern mid-latitudes simulated for each scenario. Here, deviations were equated to differences from the values
630 in the control run. The mean age of air at an altitude of 35 km increased because of weakening of the RMC and eddy
631 diffusion. The rates of increase were 0.15 and 0.20 years decade⁻¹ for scenario A and B, respectively. It has been reported
632 that an increase or decrease of the RCTT leads to an increase or decrease of “aging by mixing,” and as a result, there is
633 almost a linear relationship between the RCTT and the age of air (Garney et al., 2014). The fact that the increase in the age
634 was greater in scenario B than in scenario A was generally consistent with the results of Garney et al. (2014). In contrast,
635 the isotopic and elemental ratios were inversely correlated with the mean age of air. The fractionations increased with
636 increasing mean age in scenarios A and B, and vice versa in scenario C. Such anticorrelations between the mean age of
637 air and gravitational separations have already been reported in observations and model studies of the isotopic and
638 elemental ratios of the major components of the atmosphere (Ishidoya et al., 2013; Sugawara et al., 2018; Belikov et al.,
639 2019; Birner et al., 2020). In addition, we found that there was a tendency for the changes to be greater for light molecules
640 and smaller for heavy molecules. It is noteworthy that the value of $\psi(X/Y)$ responded differently in the A and B scenarios.
641 For example, $\psi(^{132}\text{Xe}/^{40}\text{Ar})$ decreased in Scenario A and increased in Scenario B. Furthermore, the heavier the molecule,
642 the greater the change of $\psi(X/Y)$. This result implied that the kinetic fractionations of noble gases responded differently
643 to changes of the RMC and eddy diffusion. Furthermore, the results for scenario C, where K_{zz} was increased, indicated
644 that the value of $\psi(X/Y)$ decreased significantly. The implication was that the kinetic fractionation was particularly
645 sensitive to vertical eddy diffusion. Although the deviations of $\psi(X/Y)$ shown here were so small that they could not be
646 detected with the current observational precision, the value of $\psi(X/Y)$ may be a useful tool in numerical models for
647 constraining stratospheric transport processes, especially in the case of vertical eddy diffusion.

648 In this regard, there is a discrepancy between the observed and modeled $\psi(X/Y)$ values. For example, the observed
649 $\psi(^{132}\text{Xe}/^{40}\text{Ar})$ was -0.61 ± 0.03 per meg (per meg)⁻¹, as shown in Table 1, whereas the simulated $\psi(^{132}\text{Xe}/^{40}\text{Ar})$ was
650 approximately -0.38 per meg (per meg)⁻¹. Regardless of the scenarios, there was almost no change in the overestimation
651 of $\psi(X/Y)$ values. Model results showed that $\psi(^{132}\text{Xe}/^{40}\text{Ar})$ dropped to around -0.6 per meg (per meg)⁻¹ at an altitude of
652 approximately 100 km where the molecular and eddy diffusions were competitive, but it was significantly overestimated
653 in the stratosphere. This overestimation of $\psi(X/Y)$ for noble gases in the model could be traced to the overestimation of
654 $r(X/Y)$ and was evident in the isotopic and elemental ratios of Ar, Kr, and Xe, as seen in Fig. 5b. The cause of this
655 overestimation is currently unclear. One of the possible causes would be an effect of thermal diffusion on the observed
656 data, as described before, an effect that was neglected in our model. However, we could not find clear evidence of
657 fractionations due to thermal diffusion in the stratosphere. Another possible cause could have been an unrealistic eddy
658 diffusion coefficient in the model. Although an enhancement of K_{zz} could lead to depressions of $\psi(X/Y)$, as described
659 above, the age of air would simultaneously decrease. The result would be another contradiction. These results implied
660 that our sensitivity test using arbitrary changes of transport processes could not fully reproduce realistic $\psi(X/Y)$ values.
661 To resolve this problem, it will be necessary to carry out simulations with other models. In particular, simulations of the
662 gravitational separations and kinetic fractionations, in addition to the mean age of air, using modern climate models will
663 help to validate model dynamics. Model simulations that take thermal diffusion into account will also be needed in a
664 future study.

665 **3.6 Implications for ocean heat content and noble gas thermometry of mean ocean temperature**

666 Noble gases are extremely stable in the atmosphere, but they can be exchanged between the atmosphere and ocean
667 because their solubilities in seawater change with seawater temperature variations. Because the temperature dependence
668 of solubility is unique to each noble gas, the air-sea flux of noble gases due to changes in seawater temperature changes
669 the elemental ratios of noble gases in the atmosphere (e.g. Keeling et al., 2004). Using this principle, the global mean
670 ocean temperature (MOT) over the past several hundred thousand years has been reconstructed from $\delta(\text{Kr}/\text{N}_2)$, $\delta(\text{Xe}/\text{N}_2)$
671 and $\delta(\text{Xe}/\text{Kr})$ of bubble air trapped in ice cores (e.g., Bereiter et al., 2018b; Shackleton et al., 2020; Haeberli et al., 2021).
672 Ishidoya et al. (2021) reported the long-term variations of $\delta(\text{Ar}/\text{N}_2)$ observed at ground stations in 2012 – 2020 and
673 discussed the contributions of secular changes in global ocean heat content (OHC) and BDC. They concluded that the
674 effect of the BDC change on $\delta(\text{Ar}/\text{N}_2)$ at the ground surface cannot be ignored.

675 We extended the discussion of $\delta(\text{Ar}/\text{N}_2)$ by Ishidoya et al. (2021) to $\delta(\text{Kr}/\text{Ar})$, $\delta(\text{Xe}/\text{Ar})$, and $\delta(\text{Ne}/\text{Ar})$, and roughly
676 estimated the decadal-scale effects of increased OHC on the elemental ratios of noble gases, comparing them with the
677 effects associated with BDC variations discussed in Section 3.4. The rate of change of N_2 and noble gases in response to
678 an increase in OHC depends on seawater temperature, and the relative rates of change of N_2 , Ar , Kr , Xe , and Ne per 100
679 ZJ (Zeta = 10^{21}) of OHC are reported in Table 1 of Keeling et al. (2004). Assuming a seawater temperature of 10°C, the
680 rates of change for $\delta(\text{Ar}/\text{N}_2)$, $\delta(\text{Kr}/\text{Ar})$, $\delta(\text{Xe}/\text{Ar})$, and $\delta(\text{Ne}/\text{Ar})$ are 2.56, 6.12, 19.42, and -3.91 per meg (100 ZJ) $^{-1}$,
681 respectively. The OHC value varies significantly depending on the depth of the ocean that is considered. Because we
682 mainly focus on fluctuations over a relatively short timescale in this section, we used the annual OHC data reported by
683 NOAA/NCEI up to a depth of 700 m (<https://www.ncei.noaa.gov/access/global-ocean-heat-content/index.html>, last
684 access: September 18, 2025). Using this OHC data, the average rate of change in OHC over the 10-year period from 2010
685 to 2020 was calculated as 8.4 ZJ year $^{-1}$. Therefore, the temporal change rates of $\delta(\text{Ar}/\text{N}_2)$, $\delta(\text{Kr}/\text{Ar})$, $\delta(\text{Xe}/\text{Ar})$, and
686 $\delta(\text{Ne}/\text{Ar})$ associated with the increase in OHC during this period were estimated to be 2.2, 5.1, 16.3, and -3.3 per meg
687 decade $^{-1}$, respectively. The rates of change in δ_Ω caused by the change in BDC described in Section 3.4 (increase rate in
688 Table 3) were comparable to the rates of change caused by increases in OHC. The relative magnitudes of the change rates
689 due to the BDC change to those due to the OHC increase are 66, 71, 41, and 78 % for $\delta(\text{Ar}/\text{N}_2)$, $\delta(\text{Kr}/\text{Ar})$, $\delta(\text{Xe}/\text{Ar})$, and
690 $\delta(\text{Ne}/\text{Ar})$, respectively. This result suggests that OHC and BDC variations are essential for decadal-scale variations in the
691 elemental ratios of noble gases.

692 It is interesting to determine how the BDC fluctuations can affect noble gases over the timescale of glacial-interglacial
693 cycles. Fu et al. (2020) simulated BDC during the Last Glacial Maximum (LGM) using the Whole Atmosphere
694 Community Climate Model (WACCM) and showed that the tropical upwelling during the LGM was weaker than that
695 during the modern climate and that the mean age of air increased everywhere in the stratosphere during the LGM. We
696 conducted an additional 2-D model simulation for a steady-state condition with a slow BDC in a simplified manner. The
697 RMC in the model was weakened so that the mean age of air increased by 0.3 years (approximately 9 %) at an altitude of
698 35 km over the northern mid-latitudes when the model reached steady state after spin-up calculation during the 40-year
699 period. As a result of this simulation, the changes in the annual average $\delta(\text{Ar}/\text{N}_2)$, $\delta(\text{Kr}/\text{Ar})$, $\delta(\text{Xe}/\text{Ar})$, and $\delta(\text{Ne}/\text{Ar})$ at

700 the ground surface in southern high latitudes were 2.7, 7.0, 12.8, and -4.9 per meg, respectively, compared with those
701 before changing the RMC. If the BDC changes significantly with glacial-interglacial cycles, this may be recorded in the
702 noble gas elemental ratios in ice core samples, which may need to be considered when the past MOT is reconstructed
703 from noble gases.

704 **4 Conclusions**

705 Through continued high-quality sampling of stratospheric air and advances in gas analysis technology, this study revealed
706 for the first time the existence of small fractionations of noble gases in the stratosphere. The existence of gravitational
707 separation of major components of the stratosphere has been reported in our previous studies. It is nowadays recognized
708 that stratospheric gravitational separation is a tool that can be used to diagnose stratospheric transport processes (Garny
709 et al., 2024b). In addition to documenting gravitational separations, this study quantified the kinetic fractionations of
710 noble gases and revealed ways to apply them to the validation of transport processes in numerical models. This study
711 suggested that fractionations of noble gases due to molecular diffusion may respond in a unique way to long-term changes
712 of the RMC and eddy mixing and will differ from the response of the age of air. It is therefore likely that the molecular
713 diffusion of noble gases will be incorporated into numerical models such as chemical transport models and climate models
714 in future studies, and observational results will be used to provide constraints on the validity of the transport processes in
715 the models. Some models have already included molecular diffusion, and it would not be too difficult to incorporate it
716 into other models. An advantage in the case of simulations of gravitational separations and kinetic fractionations is that
717 the theory of molecular diffusion is well understood, and there is little ambiguity. Needless to say, the age of air is the
718 most powerful tool for diagnosing stratospheric transport processes. However, unlike the “clock-tracers” used in
719 numerical models, there are no truly ideal “clock-tracers” in observations. Even the mole fractions of CO₂ and SF₆, which
720 are often used as age tracers, are associated with several uncertainties, including nonlinear tropospheric variations and
721 mesospheric losses. Gravitational separations and kinetic fractionations have the great advantage that they are truly
722 governed by only transport processes.

723 At present, observations of noble gases in the atmosphere have been quite limited. In the future, observations of noble
724 gases will be needed not only in the stratosphere but also in the troposphere. The results of analyses of firn air and bubble
725 air in ice cores have been extremely useful for understanding the fractionations associated with molecular diffusion in the
726 atmosphere. Although there is a difference between firn air and the atmosphere where molecular diffusion and eddy
727 diffusion, respectively, are dominant, many concepts such as the age of air, age distributions (equivalent to “age spectra”
728 in atmospheric studies), gravitational separations, and kinetic fractionations (gravitational disequilibrium) are applicable
729 to both studies. Research on these will continue to progress in a complementary manner. From this perspective, it has
730 been speculated that thermal diffusion, another important equilibrium fractionation in firn air, probably also occurs in the
731 atmosphere. However, the depths at which gravitational separations, kinetic fractionations, and thermal diffusion in firn
732 air prevail differ to some extent. In contrast, all of these effects may be mixed throughout the atmosphere, and the
733 fractionation processes are more complex in the atmosphere than in firn air. This study could not clearly show the

734 influence of thermal diffusion, but because the sensitivities of thermal diffusion vary as a function of the gas species, this
735 issue will likely be resolved by accumulating more observational data.

736 In this study, we improved the two-dimensional model to simultaneously calculate the mole fractions of many noble
737 gases, and we were able to basically reproduce gravitational separations and kinetic fractionations in the stratosphere.
738 However, simulations by numerical models are currently insufficient. A major problem is that we could not adequately
739 reproduce the kinetic fractionations of noble gases. The fact that the two-dimensional model used in this study
740 underestimated the strength of the kinetic fractionation suggested that observations of noble gases may provide constraints
741 on the uncertainties of the transport processes in numerical models. At present, it is difficult to detect variations of noble
742 gases elemental ratios in the troposphere caused by variations in stratospheric circulation, except for $\delta^{40}\text{Ar}/^{28}\text{N}_2$.
743 However, when considering longer timescales such as glacial-interglacial cycles, variations in stratospheric circulation
744 may have a significant impact on ice core data. It may also be necessary to incorporate thermal diffusion in future studies.
745 Future research that uses more realistic three-dimensional models to attempt to reproduce not only the age of air, but also
746 gravitational separations and kinetic fractionations of noble gases will be required.

747 **Data availability.** The observational data obtained by our balloon measurements are included as an electronic supplement
748 to this manuscript.

749 **Author contributions.** SS designed the study, conducted the balloon observations, and drafted the manuscript. IO and
750 KK conducted the measurements of heavy noble gases at the National Institute of Polar Research. SI conducted the
751 measurements of isotopic and elemental ratios of atmospheric major components and conducted the balloon observations.
752 SA, TN, SM, ST, and HH conducted the balloon observations. All authors approved the final manuscript.

753 **Competing interests.** The contact author has declared that none of the authors has any competing interests.

754 **Acknowledgements.** We deeply thank the Scientific Ballooning Research and Operation Group of the Institute of Space
755 and Astronautical Science, JAXA, Japan.

756 **Financial support.** This study was supported by Japan Society for the Promotion of Science KAKENHI grants (nos.
757 24K03070, 24H00762, 24H02345, 22H05006, 23K11396, and 23H00513).

^{136}Xe	136	32.7	47.76	1.090E-05	0.634

944 ^a Mass number of molecule. ^b Diffusion volume parameter (Reid et al., 1987). ^c Harmonic mean of mass numbers
 945 between the respective molecule and air. ^d Diffusivity of molecule X in air given by Eq. (12). These values are examples
 946 at 1000 hPa and 273 K. ^e The ratio of molecular diffusivities relative to $D_{28N_2,air}$. Note that these values are independent
 947 of temperature and pressure.

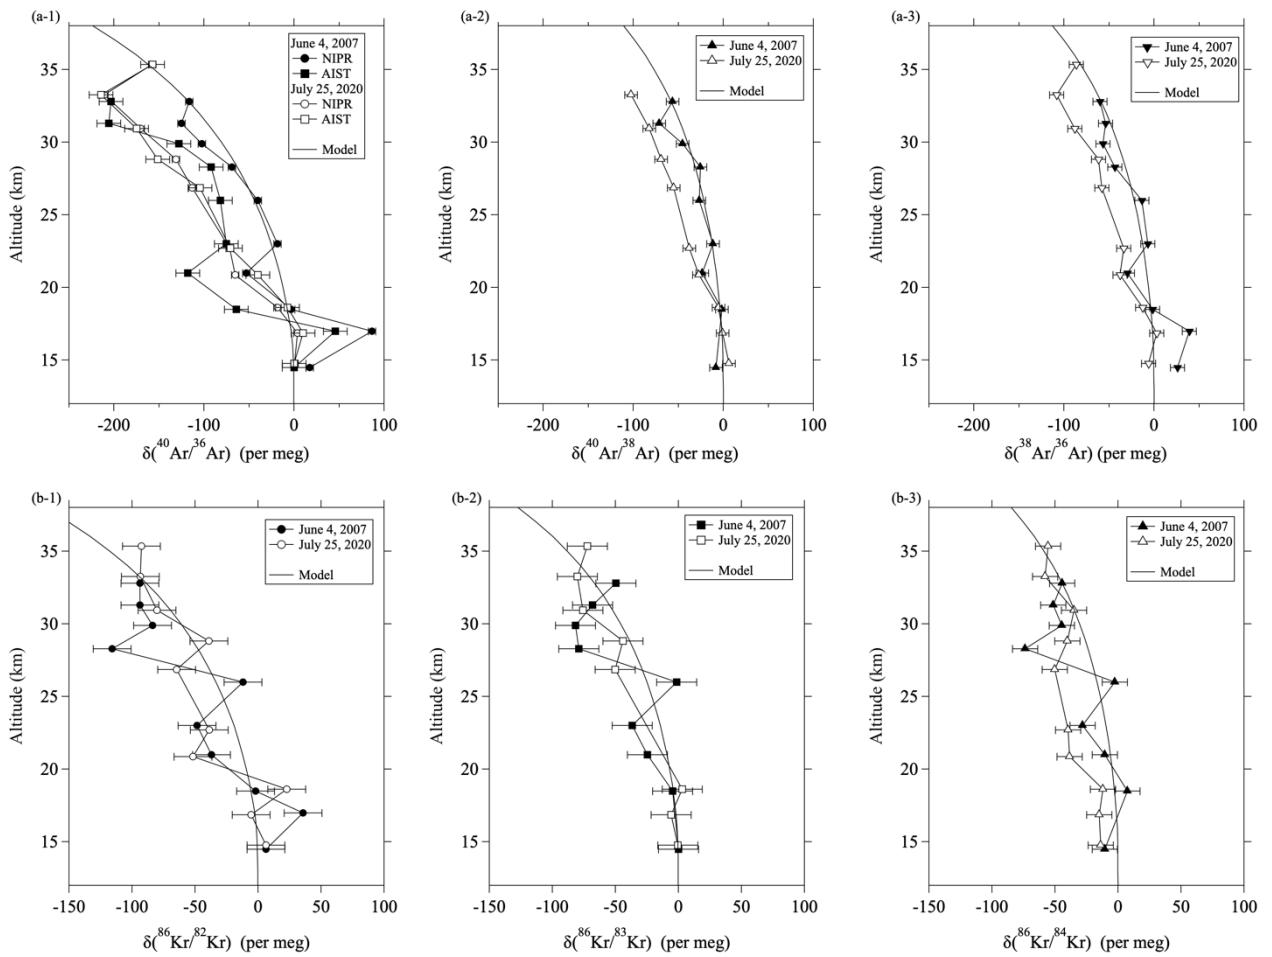

Table 3. Values of δ_Ω at 40°N on the ground surface simulated using the updated SOCRATES model.

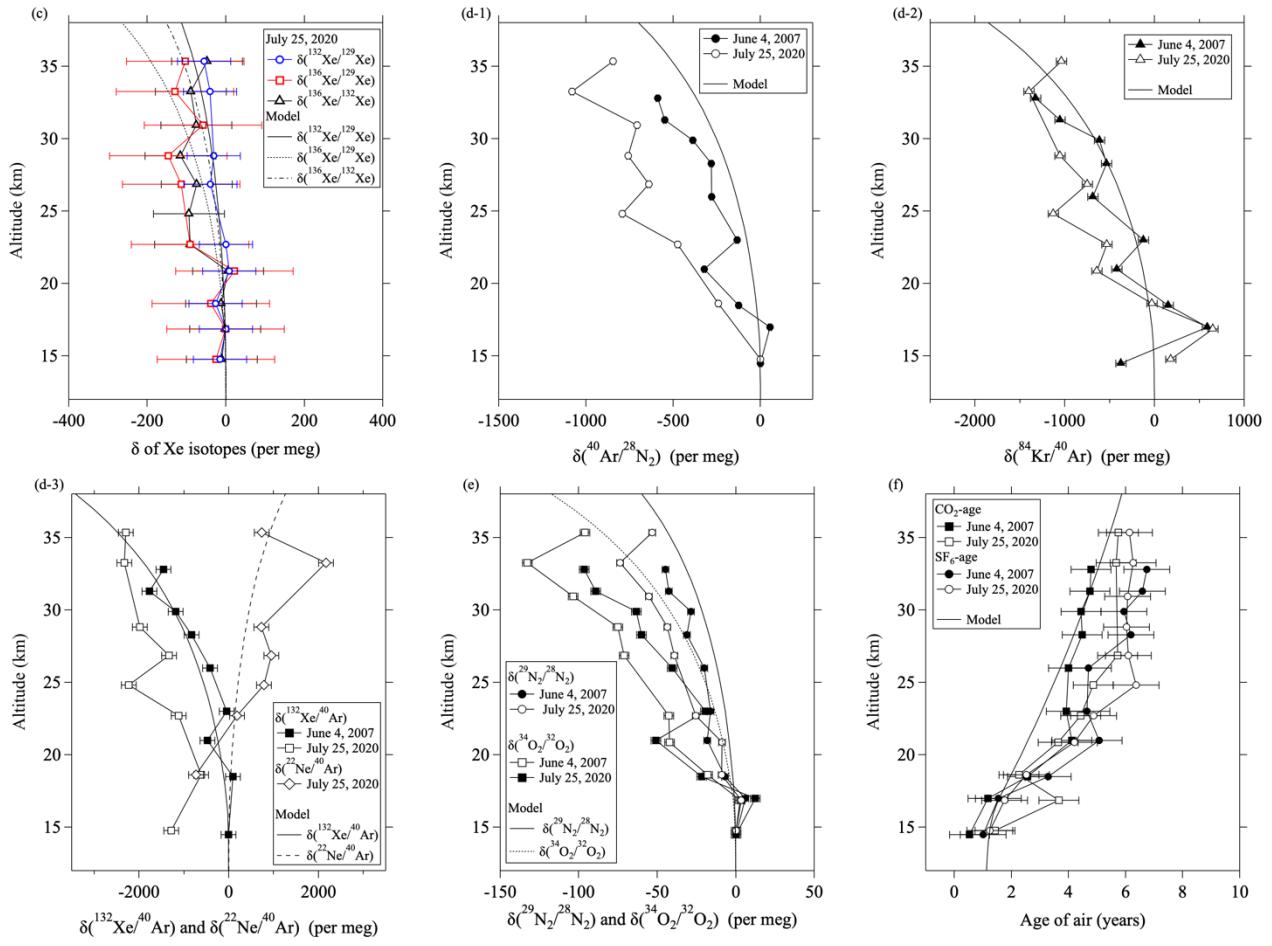

Isotopic and elemental ratio	Annual average of δ_Ω ^a (per meg)	Seasonal amplitude ^a (per meg)	Increase rate ^b (per meg decade ⁻¹)
$\delta(^{29}\text{N}_2/^{28}\text{N}_2)$	2.4	0.3	0.12
$\delta(^{34}\text{O}_2/^{32}\text{O}_2)$	4.6	0.5	0.24
$\delta(^{40}\text{Ar}/^{28}\text{N}_2)$	27.7	3.1	1.41
$\delta(^{40}\text{Ar}/^{36}\text{Ar})$	8.8	1.0	0.45
$\delta(^{40}\text{Ar}/^{38}\text{Ar})$	4.4	0.5	0.22
$\delta(^{38}\text{Ar}/^{36}\text{Ar})$	4.5	0.5	0.23
$\delta(^{86}\text{Kr}/^{82}\text{Kr})$	6.5	0.7	0.33
$\delta(^{86}\text{Kr}/^{83}\text{Kr})$	4.9	0.5	0.25
$\delta(^{86}\text{Kr}/^{84}\text{Kr})$	3.3	0.3	0.16
$\delta(^{132}\text{Xe}/^{129}\text{Xe})$	4.3	0.4	0.21
$\delta(^{136}\text{Xe}/^{129}\text{Xe})$	10.0	1.0	0.50
$\delta(^{136}\text{Xe}/^{132}\text{Xe})$	5.7	0.6	0.28
$\delta(^{84}\text{Kr}/^{40}\text{Ar})$	72.2	7.8	3.66
$\delta(^{132}\text{Xe}/^{40}\text{Ar})$	132.3	14.0	6.66
$\delta(^{22}\text{Ne}/^{40}\text{Ar})$	-50.0	5.6	-2.56

950 ^a Annual average and seasonal peak-to-peak amplitude of δ_Ω simulated for the control run. ^b Rate of secular increase of
 951 δ_Ω simulated for the weakened- residual mean circulation (RMC) scenario.

955 **Figure 1.** Comparisons of $\delta(^{40}\text{Ar}/^{36}\text{Ar})$ values measured at the National Institute of Advanced Industrial Science and
 956 Technology (AIST) and National Institute of Polar Research (NIPR) for the stratospheric air samples (closed and open
 957 squares). The results measured for H128 firn air (Oyabu et al., 2025) are also shown by open circles. The linear function
 958 $y = x$ is shown by the dotted line.

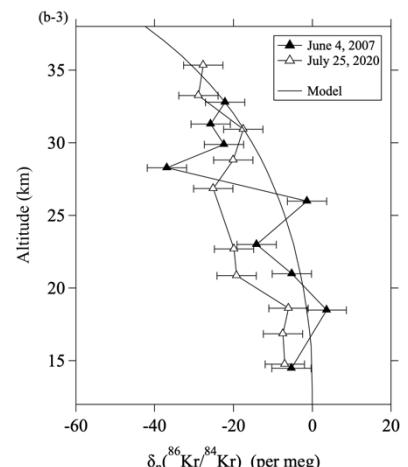

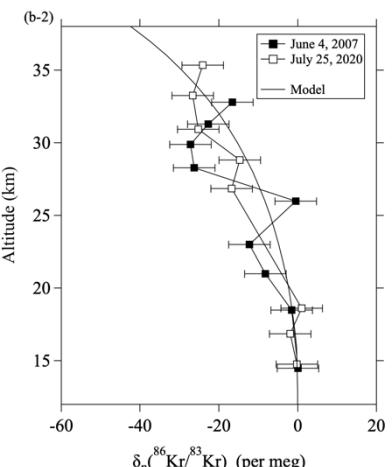

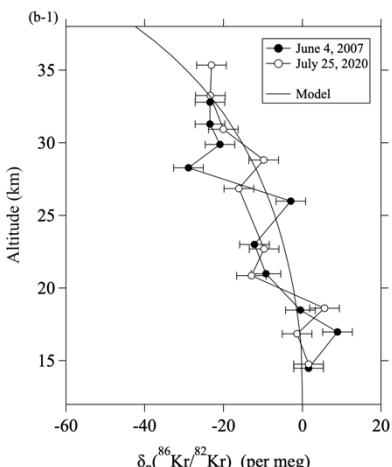

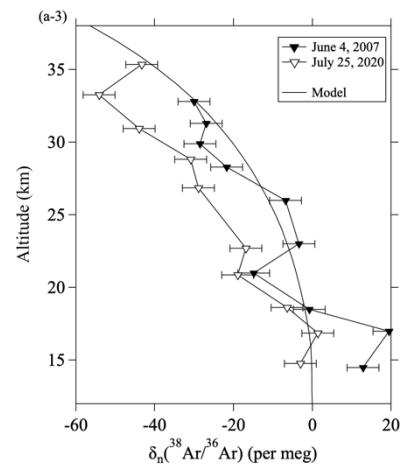

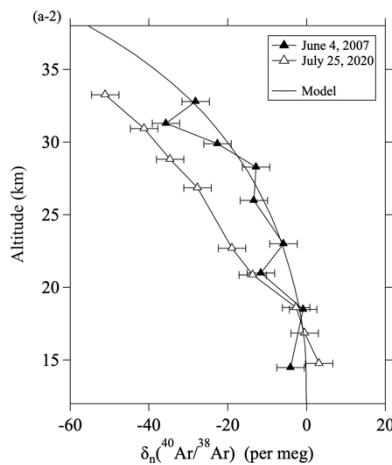

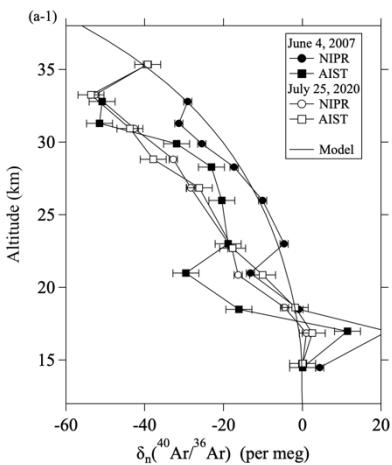

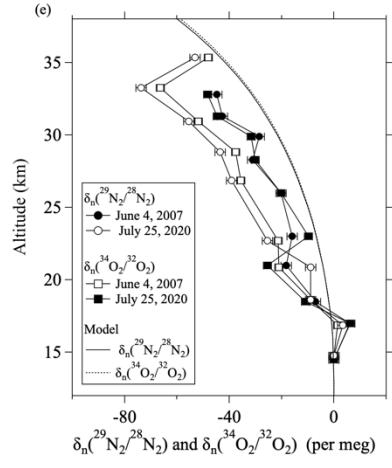

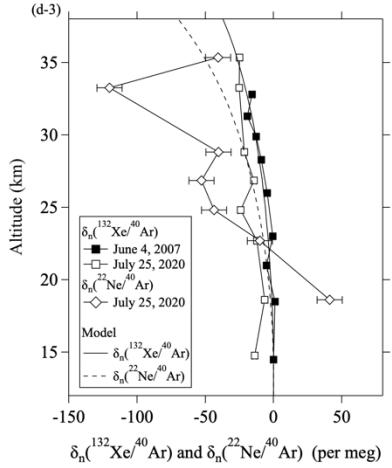

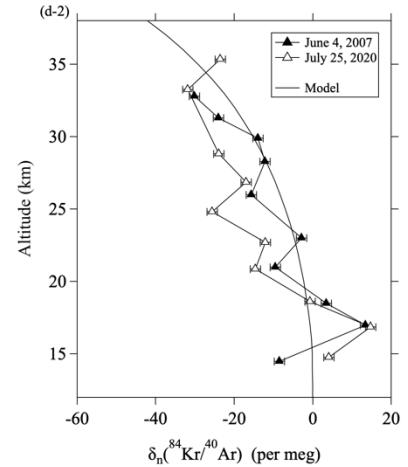

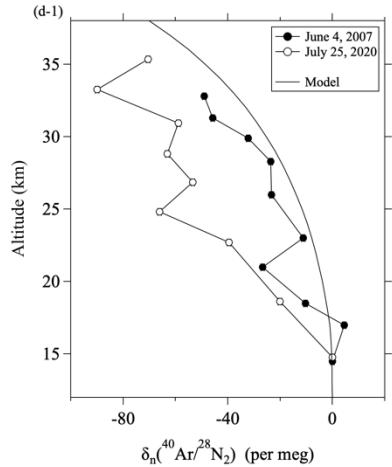

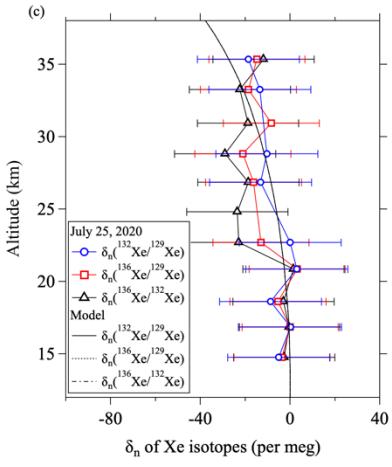

963

964 **Figure 2.** Vertical profiles of the isotopic ratios for (a-1~3) Ar, (b-1~3) Kr, and (c) Xe; (d-1~3) elemental ratios; (e)
965 is isotopic ratios of N₂ and O₂; and (f) age of air. Results of model simulations are shown by the various dotted and solid
966 lines.

967

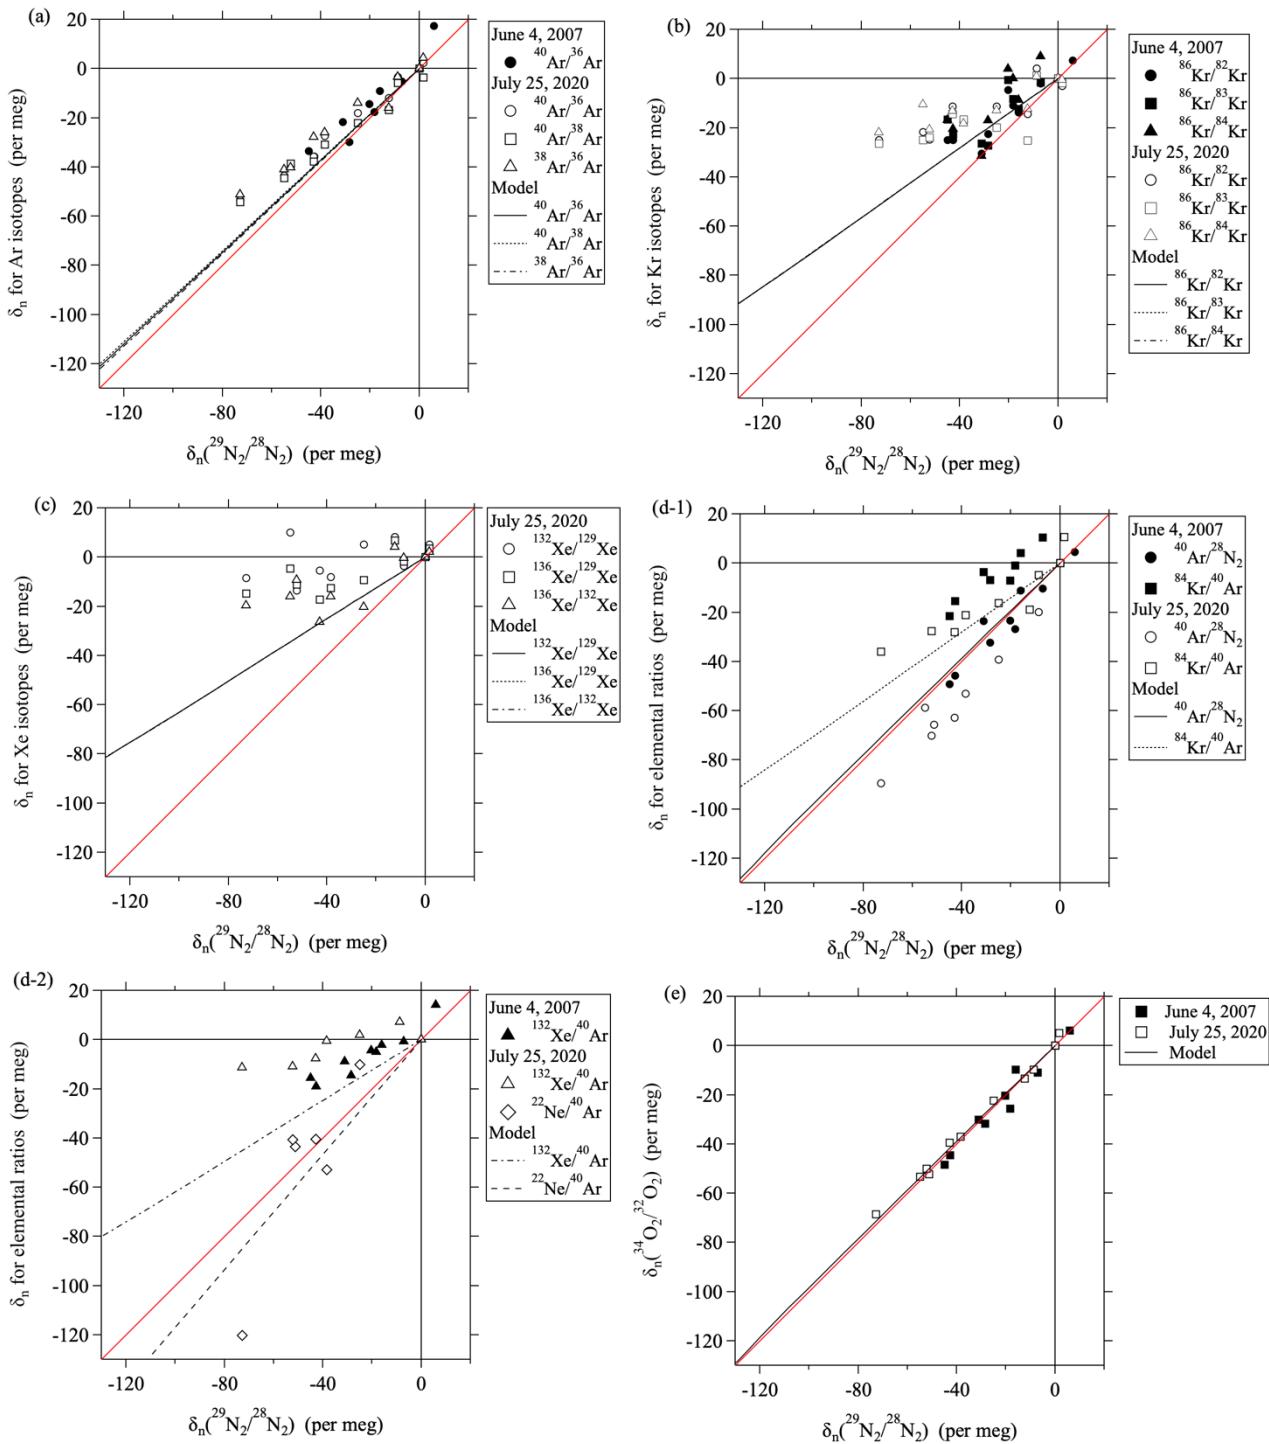

968

969

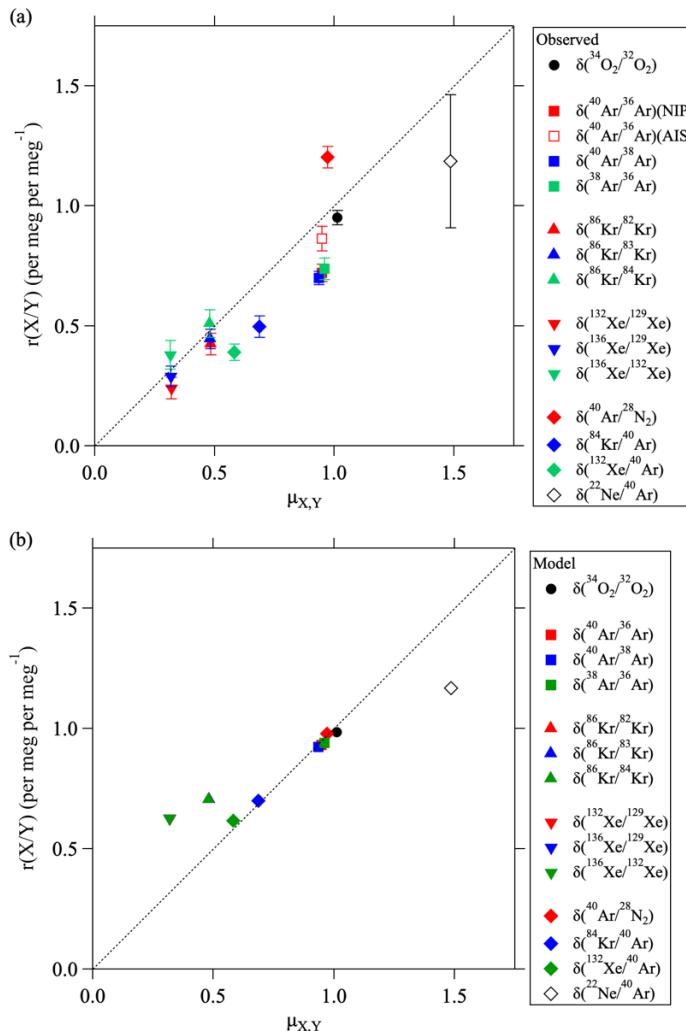

970 **Figure 3.** Same as Figure 2, but for the values normalized by the mass number differences ($\delta_n(X/Y)$).
971

975 **Figure 4.** Plots of $\delta_n(X/Y)$ versus $\delta_n(^{29}N_2/^{28}N_2)$. Black lines are linear least-squares fits to the data. Results of model
 976 simulations are shown by black lines. The mass-dependent relationships ($y = x$) are shown by red lines.

978

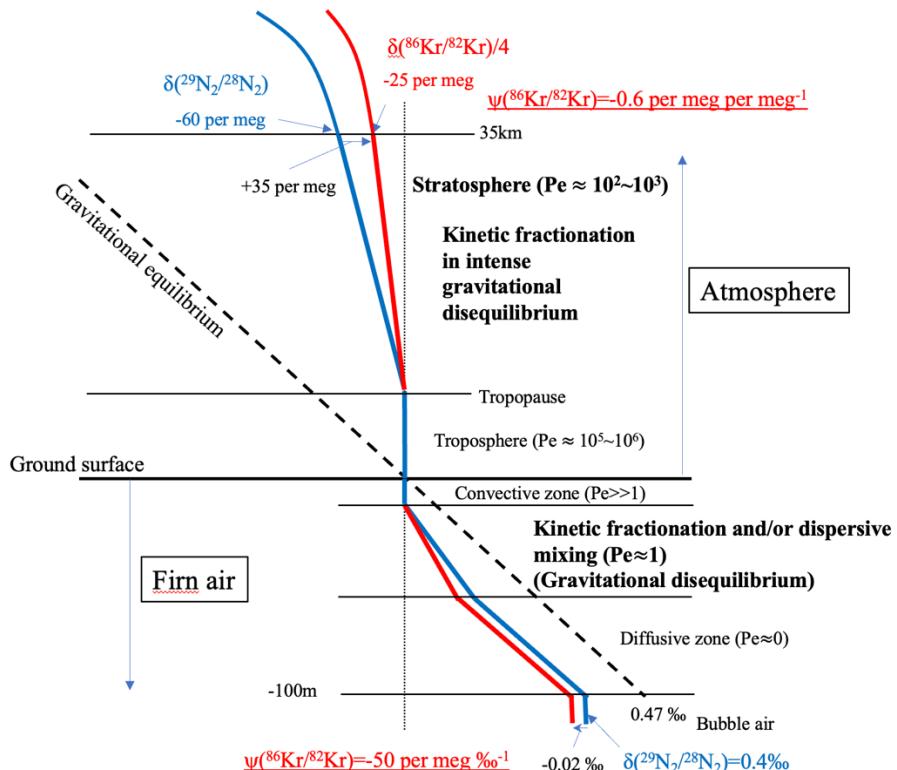

979

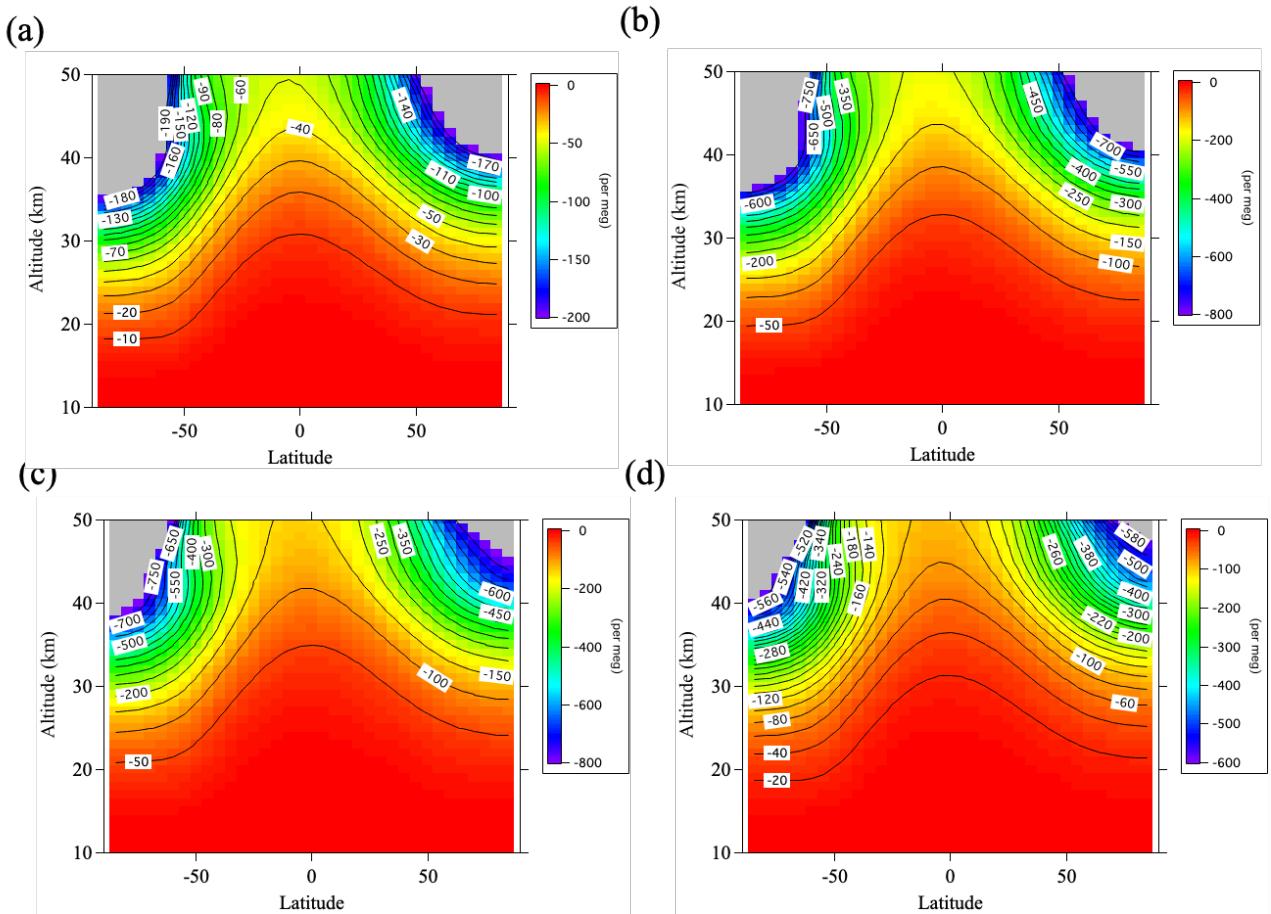

980

981 **Figure 5. (a)** Plots of the value of $r(X/Y)$ versus the molecular diffusivity factor, $\mu_{X,Y}$. Dotted line shows the linear
 982 function ($y = x$). **(b)** Same as (a), but for the results at mid-stratosphere over 40°N simulated by using a two-
 983 dimensional model.

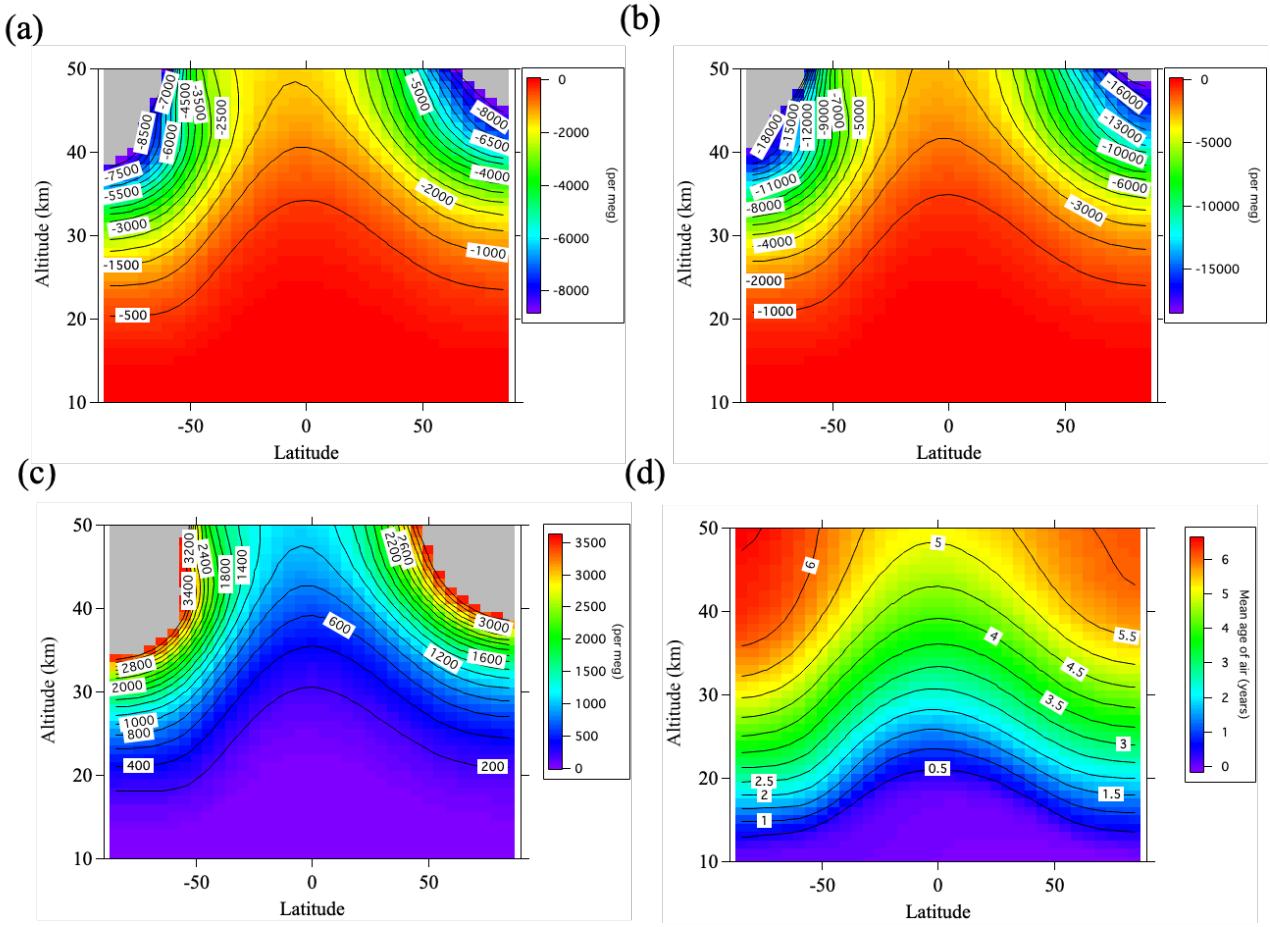

984

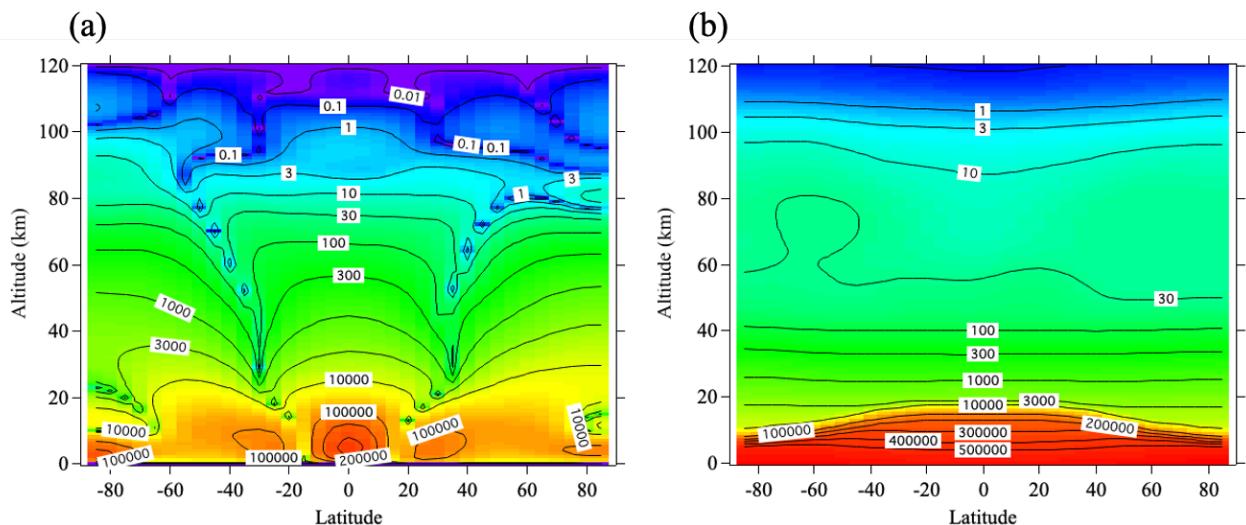

987 **Figure 6.** Schematic representation of vertical profiles of $\delta(X/Y)$ and the effects of kinetic fractionations in a firn and
 988 the stratosphere. $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, $\delta(^{86}\text{Kr}/^{82}\text{Kr})/4$, and its excess value, $\psi(^{86}\text{Kr}/^{82}\text{Kr})$, are shown as an example of the heavy
 989 nobles gases. Note that the scales of the vertical and horizontal axes differ between the firn and atmosphere.

993 **Figure 7.** Average meridional distributions in June and July for (a) $\delta(^{29}\text{N}_2/^{28}\text{N}_2)$, (b) $\delta(^{40}\text{Ar}/^{36}\text{Ar})$, (c) $\delta(^{86}\text{Kr}/^{82}\text{Kr})$, and
 994 (d) $\delta(^{132}\text{Xe}/^{129}\text{Xe})$, simulated using the updated SOCRATES model. Values lower than the lowest color contours are
 995 shown in gray.

999 **Figure 8.** Same as Fig. 7, but for (a) $\delta(^{84}\text{Kr} / ^{40}\text{Ar})$, (b) $\delta(^{132}\text{Xe} / ^{40}\text{Ar})$, (c) $\delta(^{22}\text{Ne} / ^{40}\text{Ar})$, and (d) mean age of air.

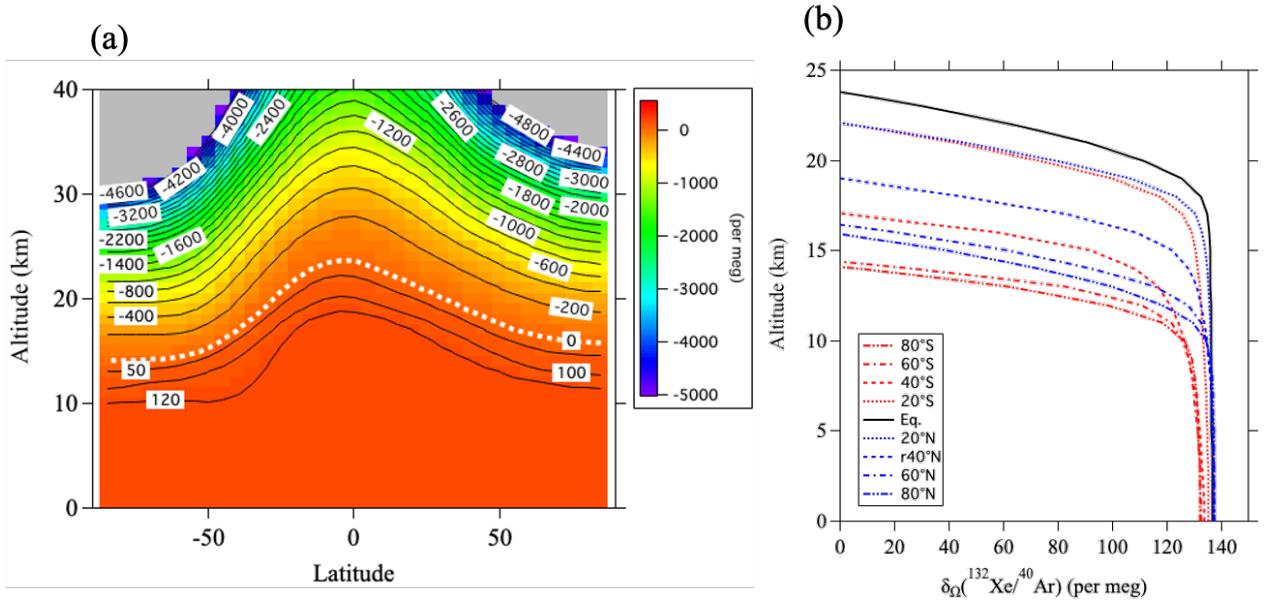

1001

1002

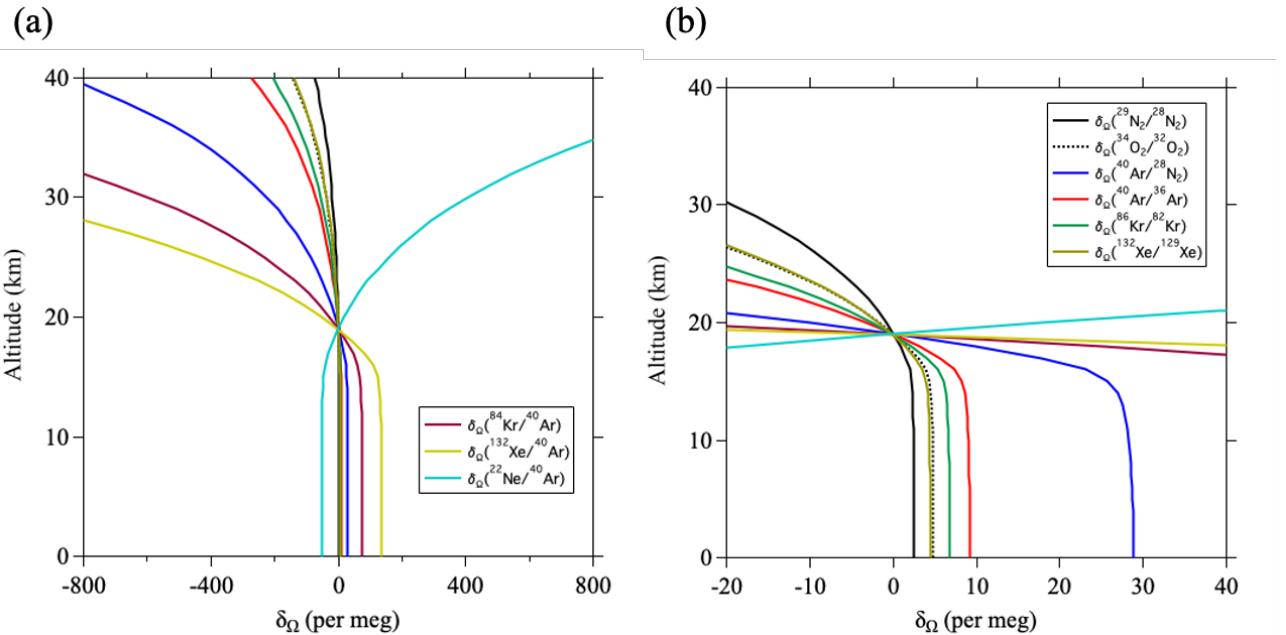

1003 **Figure 9.** Annual mean distributions of two components of the Péclet number (Pe), (a) $\text{Pe}_{28\text{N}_2,w}$ and (b) $\text{Pe}_{28\text{N}_2,K}$
1004 simulated for $^{28}\text{N}_2$ using the updated SOCRATES model.

1005

1008 **Figure 10.** (a) Same as Fig. 8b, but for the annual average of $\delta\Omega(^{132}\text{Xe}/^{40}\text{Ar})$. The altitude at which $\delta\Omega(^{132}\text{Xe}/^{40}\text{Ar})$ is
 1009 zero is shown by a white dotted line. (b) Vertical distributions of the annual average of $\delta\Omega(^{132}\text{Xe}/^{40}\text{Ar})$ at latitudes from
 1010 80°S to 80°N. Only the regions where $\delta\Omega(^{132}\text{Xe}/^{40}\text{Ar})$ is positive are shown.

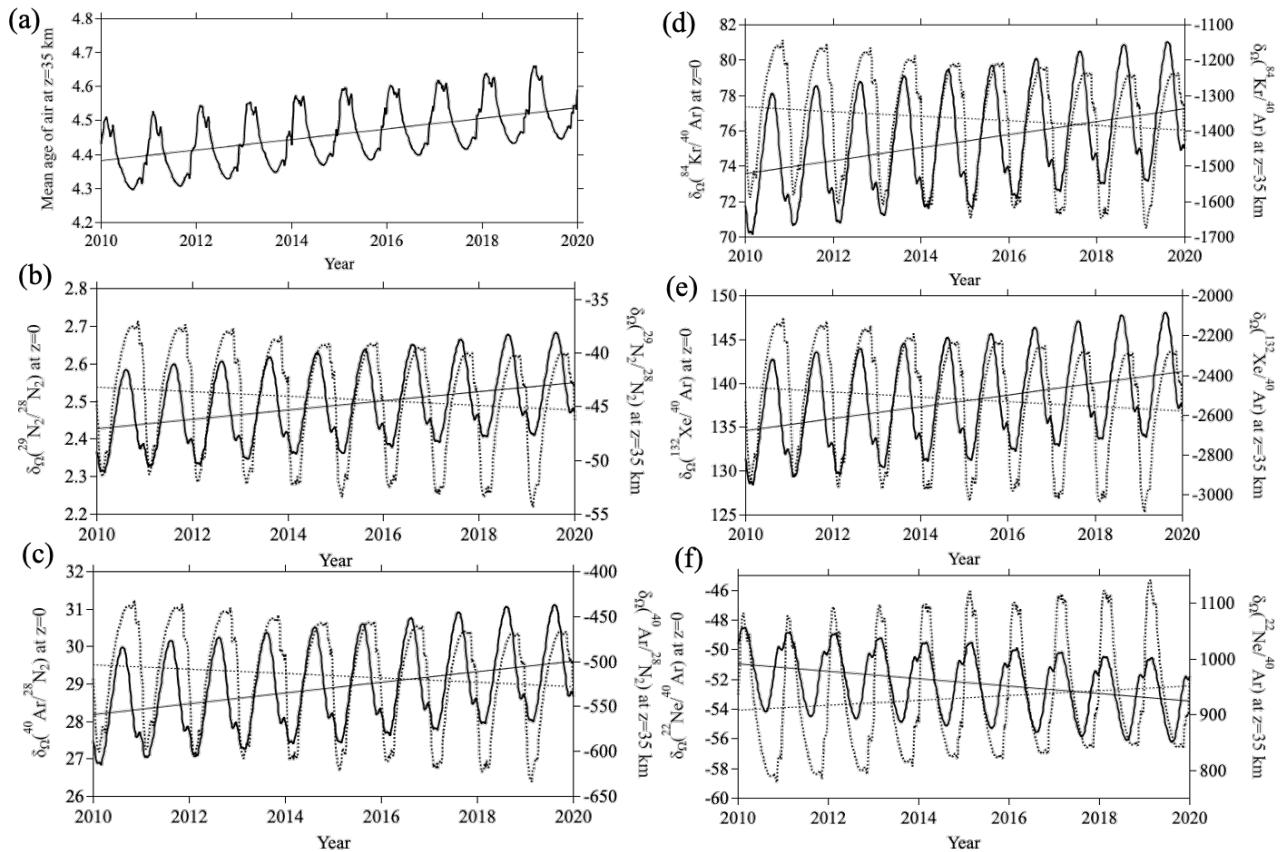

1012

1013

1014 **Figure 11.** (a) Vertical distributions of the annual average δ_{Ω} at 40°N , calculated using the updated SOCRATES model.
1015 (b) Same as (a), but the horizontal axis is expanded close to zero.

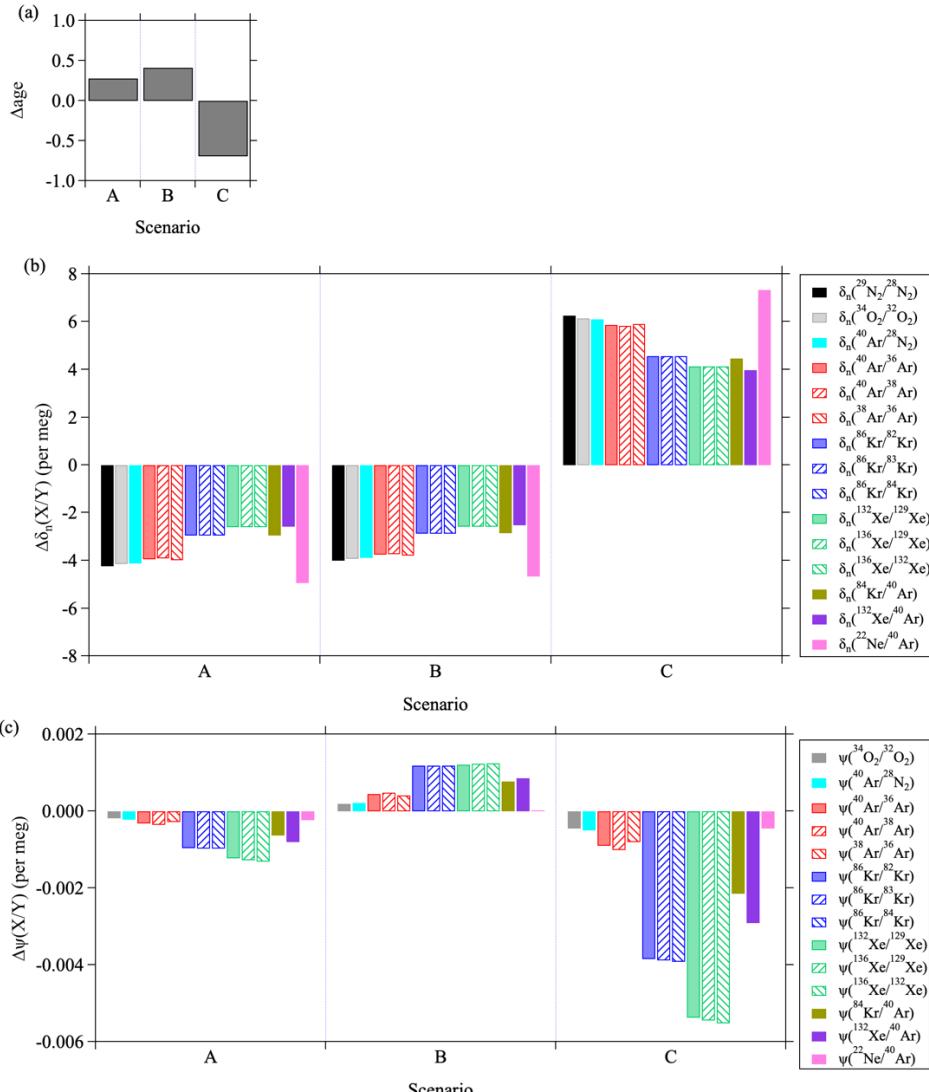

1016

1019 **Figure 12.** Temporal variations of (a) mean age of air, and (b–f) $\delta_{\Omega}(X/Y)$ values at 40°N simulated by using the updated
 1020 SOCrates two-dimensional model for the weakened-RMC scenario (see text). Thick solid lines and dotted lines in
 1021 (b)–(f) show the values at the ground surface and at an altitude of 35 km, respectively. Linear lines denote secular
 1022 trends obtained by applying linear regression analyses.

1024

1025

1026

1027

Figure 13. Deviations of (a) mean age of air, (b) $\delta_n(X/Y)$, and (c) $\psi(X/Y)$ from the values simulated in the control run.

1028

A, B, and C denote the weakened-RMC, weakened-RMC&K, and enhanced-K_{zz} scenarios, respectively (see text).

1029

Deviations are calculated from the annual mean at an altitude of 35 km over 40°N.
