**Abstract.** Ever-worsening climate change increases near-surface air temperatures for almost the entire Earth and threatens living organisms and human society. While annual mean changes are frequently used to quantify past and expected future changes, the increase is rarely uniform throughout the year. In addition, the shape of the annual cycle and its changes can differ considerably between regions around the globe. Therefore, we perform a global analysis resolving the annual cycle and its changes in different regions, focusing on diagnostics that can be evaluated for the variety of existing annual cycle shapes (e.g., single and double waves, different timing of seasons, etc.). Many previous studies relied on parameter-based methods, assuming a sinusoidal shape of the mean annual cycle. We introduce the Functional Data Analysis (FDA) approach, representing the mean annual cycle by a linear combination of Fourier bases. The FDA methodology does not require any prior assumptions about the shape of the temperature seasonal cycle except periodicity and allows to quantitatively assess various aspects of the seasonal cycle shape. The evolution of the mean annual cycle is estimated from daily long-term mean temperature values, which are converted to functional form. We concentrate on diagnostics that evaluate the absolute change in temperature, its seasonal slope, the position of the maximum, and the amplitude of the annual cycle. We analyze two reanalysis datasets (coupled CERA20C and atmospheric ERA5) and a subset of five CMIP6 Earth system models (ESMs). Observed changes in the second half of the 20th century are assessed, and the ability of ESMs to represent them is evaluated. Further, the changes projected for the end of the 21st century under the SSP3-7.0 pathway are analyzed. Among other results, we highlight distinct differences between the two reanalyses, especially over equatorial and polar regions across diagnostics. Our approach also reveals that differences in the historical period between 1951-1980 and 1981-2010 can be negative during (short) parts of the year in many regions. Further, the ESMs future projections show different rates of warming between seasons, resulting in changes in the amplitude. The largest amplitude increase is projected over the Mediterranean region, and the largest decrease over the Arctic Ocean, the latter being due to the considerably stronger warming in the northern hemisphere winter. The ESMs also project a delayed maximum near the poles and an earlier maximum in many tropical continental regions.

35 In Europe, the southern and eastern regions experienced a delay of the maximum of up to 10 days, whereas a slightly earlier  
36 maximum is found for northern Europe. A similar dipole pattern can be seen between eastern and western regions in North  
37 America. Regarding the slope of the annual cycle, higher latitudes detect a higher magnitude of change in the historical period  
38 than lower latitudes. The geographical pattern remains the same for future slope changes, with the magnitude twice as high in  
39 most regions. The FDA diagnostics introduced here can be tailored for different purposes and applied to different climatic  
40 variables, with no need to make any prior assumptions about the annual cycle shape. Potential applications include, e.g.,  
41 explicitly evaluating the climate model performance or ensemble mean and spread assessment beyond annual or seasonal  
42 means.

## 43 **1 Introduction**

44 Increasing near-surface air temperature is observed and projected for almost the entire Earth (IPCC, 2021), threatening the  
45 environment and human society alike. However, this temperature increase is rarely uniform throughout the year, and even in  
46 case the annual mean changes only slightly, the annual cycle might change quite dramatically (Marvel et al., 2021; Wang et  
47 al., 2021). The changes in seasonal temperature cycle can have potentially large impacts on, e.g., phenological phases of living  
48 organisms, agriculture, health, tourism, and other sectors. Widespread expected changes in the annual cycle have even  
49 motivated suggestions of new definitions of seasons (Hekmatzadeh et al., 2020; Wang et al., 2021; López-Franca et al., 2022).  
50 Moreover, as noted by McKinon and Huybers (2024), the shape of the temperature annual cycle can be taken as an analogy  
51 for temperature changes in general, as it is easily distinguishable from internal variability and can be reliably observed. They  
52 emphasize that the seasonality of temperature in the current climate and its changes are strongly related to projected  
53 temperature changes, and recent changes in the mean annual cycle can be considered as a proxy for overall future warming.  
54 The skill of climate models in depicting correctly the observed shape of the annual cycle and its changes is therefore very  
55 informative in terms of confidence in simulated future changes (Lynch et al., 2016).

56 A large number of previous studies have shown that the observed shape of the temperature annual cycle has already changed  
57 in recent decades, including, e.g., a phase shift towards an earlier onset of the seasons over the middle and higher latitudes  
58 (evaluated using the sinusoidal approximation of the mean annual cycle shape, the results do not relate to a specific season,  
59 Stine et al., 2009), lengthening of summer (Peña-Ortiz et al., 2015; Park et al., 2018) and shortening of all other seasons over  
60 Northern Hemisphere midlatitudes (Wang et al., 2021). Wang and Dillon (2014) revealed regionally different changes of  
61 annual cycle amplitude over northern hemisphere midlatitudes and polar regions, with a prevailing decrease in 1975-2010 in  
62 comparison to 1961-1990. In addition to adaptation to recently observed shifts, it is also crucial to investigate the expected  
63 future evolution, as the shape of the annual cycle is expected to undergo even more dramatic changes during the upcoming  
64 decades. For example, Santer et al. (2018, 2022) found an increase in the temperature amplitude globally and throughout the  
65 troposphere in recent observations and future projections and attributed it to anthropogenic forcing. Further, Chen et al. (2019)  
66 concluded that the CMIP5 global climate models project increased seasonal amplitudes in low-latitude regions and most global

67 ocean areas. In contrast, the seasonal amplitudes are expected to decrease over the Southern Ocean and high-latitude regions.  
68 Ruosteenoja et al. (2020) describe projected lengthening of the summer season in Northern Europe and López de la Franca et  
69 al. (2013) show the same for Spain, together with the winter season practically disappearing.  
70 Earth system models (ESMs) are state-of-the-art instruments for assessing possible future climate evolutions and attributing  
71 observed and projected climate changes to their potential causes. The multi-model ensemble produced under the Coupled  
72 Model Intercomparison Project Phase 6 (CMIP6) initiative, coordinated by the World Climate Research Programme's (WCRP)  
73 Working Group on Coupled Modelling (Eyring et al., 2016), represents the newest set of ESM simulations. This ensemble  
74 includes simulations of a range of different models under several shared socioeconomic pathways (SSPs, Tebaldi et al., 2021,)   
75 enabling the analysis of uncertainties arising from structural model differences (Abramowitz et al., 2019). Indeed, despite  
76 indisputable progress in the complexity of the newest generation ESMs, many uncertainties and issues still need to be solved  
77 (Shaw and Stevens, 2025; Randall et al., 2019; Bordoni et al., 2024). The issue of the choice of ESMs appropriate for climate  
78 change scenarios is a very complex task, and different approaches are still under investigation (e.g., McDonnell et al., 2024;  
79 Snyder et al., 2024; Merrifield et al., 2023; Rahimpour Asenjan et al., 2023).

80 The shape of the annual cycle of air temperature differs significantly among different regions around the globe. Therefore,  
81 performing a global analysis requires focusing on quantities that can be evaluated for all these different shapes (e.g., single  
82 and double waves, different timing of seasons, etc.). A lot of previous studies relied on Fourier-transform-based methods,  
83 assuming a sinusoidal shape of the mean annual cycle and focused on its amplitude and phase (e.g., in Paluš et al., 2005, Stine  
84 et al., 2009, Zhao et al., 2021, Marvel et al., 2021, Deng and Fu, 2023, Zhang et al., 2025), which in some cases resulted in  
85 omitting certain regions (e.g., Dwyer et al., 2012, Yettella and England, 2018) and a large portion of studies focused on the  
86 northern hemisphere only. Here, we introduce an innovative approach based on Functional Data Analysis (FDA). The  
87 evolution of temperature throughout the year is approximated by daily long-term mean temperature values, which are  
88 converted to functional form (see Section 3 for details). This approach allows us to assess any existing shape of the temperature  
89 seasonal cycle. López-Franca et al. (2022) also employed smoothing of daily temperature values with splines and assessed  
90 changes in dates of minimum and maximum of the smoothed annual cycle, as well as the dates of minimum and maximum  
91 slope changes. Unlike the methodology presented here, they only concentrated on specific parts of the year and on the  
92 midlatitude regions. We previously successfully applied a Functional data analysis approach to investigate the influence of  
93 driving the global climate model on nested regional climate simulation within a multi-model ensemble (Holtanová et al., 2019).

## 94 **2 Data**

95 The present study deals with the annual cycle of daily mean near-surface air temperature. To analyze its recent changes  
96 over both land and ocean regions, we use two reanalysis datasets from the European Centre for Medium-Range Weather  
97 Forecasts (ECMWF), namely the ERA5 (Hersbach et al., 2020) and CERA20C (Laloyaux et al., 2018). The choice was  
98 motivated by the long temporal coverage of these datasets back to the 1950s. Some basic information about these datasets is

99 described in Table 1. One of the main differences between them is that ERA5 is an atmospheric reanalysis; in contrast,  
100 CERA20C was created using a coupled modeling system with the representation of not only the atmosphere but also the ocean,  
101 land, oceanic waves, and sea ice. The atmospheric modeling system (ECMWF’s Integrated Forecast System (IFS) version  
102 CY41R2) is the same for both ERA5 and CERA20C (Laloyaux et al., 2018; Hersbach et al., 2020). As the coupling demands  
103 large computational costs, CERA20C has a coarser horizontal resolution (Tab. 1). The CERA20C dataset includes 10 members  
104 representing the spread related to the errors in the assimilated observations and the modeling system (Laloyaux et al., 2018).  
105 We use the “number0” ensemble member and do not analyze the uncertainty spread here.  
106 Further, we select historical and scenario simulations of five CMIP6 ESMs (Table 2). The model choice is motivated by the  
107 different values of the equilibrium climate sensitivity (Meehl et al., 2020) and overall good performance compared to the whole  
108 CMIP6 ensemble (Bock et al., 2020). We employ only five models to be able to analyze the individual simulated curves of the  
109 mean annual cycle and illustrate the innovative methodology properly. For the scenario period, we analyze outputs for the  
110 SSP3-7.0 socio-economic pathway, which represents the medium to high end of the whole range of the SSPs currently  
111 considered plausible (Tebaldi et al., 2021).  
112 The analysis focuses on the time periods described in Table 3. The two historical periods are used for the assessment of recent  
113 observed changes (Section 4.1). The difference between the future and reference periods is referred to as the projected or  
114 expected future change (described in Section 4.2). For both the reanalyses and ESMs, the long-term mean values of near-  
115 surface air temperature for each day of the year are averaged over the reference regions from Working Group 1 of the IPCC  
116 AR6 (Iturbide et al. 2020) directly from the native grids. These daily long-term mean values are then subject to functional  
117 data analysis as described in the following section. To enable comparison of our results to global mean, annual mean  
118 temperature changes, the supplementary Table S01 lists these changes for both the historical and future time periods, with  
119 additional division into land and ocean areas.

### 120 **3 Functional data analysis approach**

#### 121 **3.1 Construction of the functional data**

122 The modeling of the mean seasonal cycle of temperature uses the techniques of Functional Data Analysis (FDA), a relatively  
123 novel statistical approach (Ramsay and Silverman, 2005; Horváth and Kokoszka, 2012; Kokoszka and Reimherr, 2017). Unlike  
124 traditional statistics, a single observation of a variable is not a data point but rather a function. This approach is especially  
125 suitable for a series of observations with an underlying correlation structure.

126 In general, the relation between a covariate  $x$  and a response  $Y$  can be modeled as a function  $y = f(x)$  using the pairs  $(x_i, Y_i)$   
127 of the data,  $i = 1, \dots, n$ . In our case, the covariate  $x$  is represented by the days of the year ( $x_i$  varies from 1 to 365, for leap years,  
128 values for February 29 were deleted). The mean seasonal cycle of temperature plays the role of response  $Y$ . To account for the  
129 periodic nature of the data, the function  $f(x)$  is defined as a linear combination of Fourier basis functions:

$$f(x) = a_0 + \sum_{n=1}^m \left( a_n \cos \cos \frac{n\pi x}{365} + b_n \sin \sin \frac{n\pi x}{365} \right) \quad (1)$$

i.e.,  $f(x)$  depends on  $K=2m+1$  coefficients  $\{a_0, a_1, b_1, \dots, a_m, b_m\}$  and basis functions (see Fig. 1a for  $K=5$ ).

The coefficients  $\{a_0, a_1, b_1, \dots, a_m, b_m\}$  are chosen to minimize the following functional:

$$\sum_{i=1}^n [Y_i - f(x_i)]^2 \quad (2)$$

Our approach fits a function  $f$  with varying degrees of freedom to the data. In contrast to a simple interpolation, this does not necessarily mean that the function just connects all adjacent data points (i.e., in all cases where the degrees of freedom are less than the number of data points, see Fig. 1). In general, the particular values,  $x_i$ , of the covariate and the corresponding observed responses,  $Y_i$ , are linked by  $Y_i = f(x_i) + \epsilon_i$ ,  $i = 1, \dots, m$ , where  $\epsilon_i$  are realizations of the random errors. This corresponds to the situation where the covariate,  $x_i$ , is given, and the observed response,  $Y_i$ , is the realization of some random variable linked with the value of  $x_i$ . The resulting function  $f$  balances the size of the errors,  $\epsilon_i$ , and the smoothness of the function linking the covariate and the response. The smaller the number of basis functions  $K$  is, the less sensitive it is to fluctuations in the data – compare panels (b) and (d) in Fig. 1 for cases  $K=5$  and  $K=55$ . Here we choose  $K=15$ . The choice is supported by the fact that for this value, the character of the FDA curve best resembles the 30-day running average. The 30-day average is analogous to the monthly mean, and the length of the month is an intuitive choice in climatology, as generally a lot of climatological analysis is based on monthly mean values. Moreover, even for  $K=5$ , the FDA function explains more than 99% of the variance of the 30-year mean values of temperature, even though the curve does not entirely align with the underlying data (Fig. 1(b)). On the other hand, for higher  $K$ , the curve becomes too fluctuating, resembling high inter-daily variability in the data. Therefore, we consider smoothing based on  $K=15$  appropriate for the current study. However, the results of the analysis are not sensitive to the choice of  $K$  (not shown). The FDA-smoothed curves of the mean annual cycle for all the datasets and geographical regions are shown in the supplemental Fig. S03 and S07 for the historical periods, and in Fig. S4 and S8 for the projections.

### 3.2 FDA diagnostics

Drawing on the FDA representation of the annual cycle in each of the time periods specified in Table 3, we now define diagnostics that evaluate changes in the shape of the annual cycle (sections 3.2.1 - 3.2.5). Fig. 2 illustrates the interpretation of the diagnostics on example data. Table 4 provides an overview of the diagnostics and references to the figures showing the results based on them. All the diagnostics are further used to quantify differences between the annual cycle curves in the two historical periods and between the future and reference periods. For the historical periods, we compare the GCMs with ERA5 and CERA20C. For future time periods, we compare individual GCMs with their multi-model mean. We want to emphasize that in the projections, the multimodel mean values are based on the multimodel mean annual cycle, not the multimodel mean of the FDA diagnostics. Therefore, the multimodel mean values of FDA diagnostics can fall outside the range of individual ESMs. Regarding the terminology, we note that we use both terms “seasonal cycle” and “annual cycle” intermittently in the text, with no difference in its meaning.

161 **3.2.1 Annually integrated temperature change**

162 For each day of the year, we calculate the distances between the smoothed annual cycle curves (see Fig. 2 (a)). We then  
163 aggregate these distances in three ways: by calculating the 10th and 90th percentiles and the root mean square of them. The  
164 former two diagnostics, hence, represent high and low annual extremes of the temperature changes (allowing both positive and  
165 negative values), while the latter diagnostic evaluates the Euclidean distance of the whole annual cycles (positive by definition).  
166 Supplemental Fig. S1 and S2 show the occurrence of values below/above 10th/90th percentiles; the red dashed line represents  
167 the 10th percentile, and the green dashed line represents the 90th percentile. For all values below/above the 10th/90th percentile  
168 threshold, the time periods of the year when these values occur are shown in red/green.

169 **3.2.2 Annual cycle maximum**

170 We define the shift in the annual cycle maximum as the number of days between the maximum of the annual cycle in two  
171 periods (black arrow in Fig. 2(b)). Positive values indicate a delay in the maximum occurrence relative to the reference period,  
172 and negative values vice versa. In regions with two (local) maxima in the annual cycle, the “first” and “second” maxima are  
173 considered chronologically from January 1st, with no regard to the actual maximum magnitude (the second maximum can  
174 potentially have a higher temperature than the first). There are nine regions, where we identify two distinct maxima, see Fig.  
175 5, 6, S03, S04.

176 **3.2.3 Annual cycle velocity**

177 We calculate 1st derivative of the smoothed curve of the temperature annual cycle. We define temperature velocity as the  
178 absolute value of this 1st derivative curve. It gives an indication of the steepness of the annual cycle on individual days (see  
179 Fig. 2 (c)). Then we calculate changes in temperature velocities between corresponding days of the year between the two time  
180 periods. Positive differences in temperature velocity, hence, indicate days where the annual cycle is getting steeper compared  
181 to the reference period, and vice versa for negative values. Note that steepness means faster warming as well as faster cooling  
182 because we consider absolute values of the 1st derivative. Similarly to the changes in temperature itself (3.2.1), we calculate  
183 the 10th and 90th percentiles of the differences and their root mean square.

184 **3.2.4 Annual cycle amplitude**

185 The amplitude of the annual cycle is defined as the difference between the maximum and the minimum value in °C (see Fig.  
186 2 (d)). Here we evaluate the change in the amplitude between two time periods. Consequently, a positive change in the  
187 amplitude indicates an increasing temperature range over the year compared to the reference.

188 **4. Results**

189 Here, we discuss changes in the four diagnostics from a high-level perspective; detailed figures for each of the regions can be  
190 found in the Supplement (see Table 4 for an overview).

191 **4.1 Annually integrated changes in the annual cycle**

192 In the often employed annual-mean view, warming is evident almost everywhere on the globe, with land areas and higher  
193 latitudes generally warming faster (Gulev et al., 2021). Our approach resolves seasonal differences in the long-term warming  
194 signal and reveals that differences in the historical period between 1951-1980 and 1981-2010 can be negative during (short)  
195 parts of the year in many regions (Fig. 3b). This is compensated by a strong warming in other parts of the year, which can  
196 exceed 2 °C in many northern hemisphere land regions (Fig. 3c).

197 Fig. 3a shows the resulting annually integrated temperature change as the root-mean-square of the daily differences (RMSD,  
198 also termed Euclidean distance), which also exceed 1.5 °C in most datasets at northern mid-latitude land regions. In most other  
199 parts of the world, except Antarctica, the RMSD remains lower than 1.5 °C for the historical periods. We stress that this  
200 diagnostic embraces both negative and positive temperature changes, evaluating the overall change in temperature, unlike  
201 simply averaging the changes over the year.

202 With regard to warming between the historical periods, in general, a stronger signal is seen in the northern hemisphere than in  
203 the southern hemisphere. An exception is the strong warming signal in CERA20C in Antarctica (Fig. 3). Larger disagreement  
204 between the reanalyses also occurs over the southern ocean and in some regions near the equator (e.g., SAH and ARP).

205 With regard to the timing, both reanalyses show the highest temperature increase during northern-hemisphere winter, or the  
206 changes do not have any distinct maximum/minimum (Fig. S1). Only in New Zealand (NZ), the Southern Ocean (SOO), and  
207 Antarctica (WAN and EAN) are the changes larger in the southern-hemisphere winter. In the ESMs, the timing of the largest  
208 increase/decrease often does not match the reanalyses (e.g., over Greenland, the reanalyses show a decrease of temperature in  
209 the first three months of the year, whereas the ESMs show the decrease (if any) later in the year, Fig. S1). In the Arctic region  
210 (ARO), the ESMs and reanalyses generally agree that the lowest increase in temperature occurs in summer. The timing of the  
211 changes projected for the end of the century shows a distinct difference between the regions in the northern middle latitudes  
212 and subtropical areas. In the former (e.g., NEU, EEU, NWN, NEN), the highest changes occur during winter, and the latter  
213 (e.g. MED, WCA, CNA, ENA) during late summer or autumn (see Fig. S2).

214 For the warming at the end of the 21st century, the Arctic stands out with temperature increase exceeding 10 °C in all models  
215 during the 10% of strongest warming days (Fig. 4c). Such stronger warming in the polar regions compared to lower latitudes  
216 (often referred to as polar amplification) is consistent with theoretical considerations and historical observations (e.g., Stuecker  
217 et al., 2018; Previdi et al., 2021). Here, we show that the stronger warming at high latitudes predominantly comes from the  
218 upper end of the annual temperature distribution, with the 10th percentile of changes being mostly uniform across latitudes  
219 (Fig. 3b and 4b).

220 Polar amplification has also been reported to be underestimated in CMIP6 models (Casado et al., 2023) and to be weaker in  
221 Antarctica than in the Arctic region in both observations and CMIP6 models (e.g., Zhang et al., 2023; Xie et al., 2022). Our  
222 results contradict these results to some extent. Mainly, the five ESMs simulate the magnitude of historical warming in the  
223 Arctic, higher or comparable to the reanalyses (Fig. 3). Finally, we note that in the historical period, one of the two observation-  
224 based reanalyses, CERA20C, shows stronger warming in Antarctica than in the Arctic, contradicting. This discrepancy might  
225 be attributable to high decadal variability in Antarctica (Casado et al., 2023) and large uncertainties of the reanalysis outputs  
226 over this remote region with low density of assimilated observations (Laloyaux et al., 2018).

#### 227 **4.2 Shift of the annual cycle maximum**

228 For the end of the 21st century, the five selected ESMs project a delayed maximum near the poles and an earlier maximum in  
229 many tropical continental regions (Fig. 6). The shift of the maximum between the two historical periods does not show such  
230 distinct pattern (Fig. 5). In Europe, the southern and eastern regions experienced a delay of maximum of up to 10 days,  
231 whereas northern Europe a slightly earlier maximum. In North America, a similar dipole pattern of historical changes is seen  
232 between eastern and western regions (Fig. 5).

233 The largest differences between the reanalyses and ESMs are found over southern America and eastern and southern Africa  
234 (Fig. 5). Also, in the land regions near the equator, there is a disagreement between the two reanalyses (e.g., WSAF, MDG,  
235 ESAF in Africa, and NWS and SAM in South America). This is mainly due to the fact that the annual cycle has no distinct  
236 maximum peak and the warm season part of the annual cycle is rather flat; thus, a small temperature change in this season may  
237 result in a large shift of the maximum (Fig. S3). In North-Central America (NCA), even though it is farther from the equator,  
238 CERA20C gives a large shift of the maximum, but the actual temperature change is small, similar to regions NWS and SAM  
239 in South America, which are closer to the equator. In most of the regions further from the equator, the reanalyses agree on the  
240 sign of the shift in the maximum. In the oceanic regions near the equator, the reanalyses show a shift to an earlier onset of the  
241 maximum. Both between the two historical periods and between the reference and future period, we see a smaller shift of the  
242 maximum in Antarctica than in the Arctic (Fig. 5, 6).

243 In the regions near the equator, there are two distinct maxima of the annual cycle (Fig. S3, S4); therefore, we evaluate the shift  
244 also for the second maximum (Fig. 5). We stress that the first/second refers to the earlier/later occurrence during the year, not  
245 to the magnitude. In some of these regions, the annual cycle has even more “maxima”; it is modulated by at least three peaks  
246 (Fig. S3, e.g., CNRM-ESM2 in north-eastern Africa (NEAF)). As the amplitude of the annual cycle is generally low in near-  
247 equator regions, the whole curves are rather flat, and it is difficult to compare them between the datasets. For example, in the  
248 oceanic part of south-eastern Asia (SEA region), the CERA20C reanalysis shows a large shift in the 2nd maximum (Fig. 5).  
249 However, in Fig. S3 it is clear that in the first historical period, the annual cycle near the 2nd maximum is very flat, and  
250 therefore the large shift rather indicates a clearer emergence of the 2nd maximum. Also, in north-eastern Africa (NEAF), the  
251 evaluation of the maximum shift is rather problematic. The maxima in different ESMs and reanalyses are shifted, so it is  
252 actually questionable to compare them (Fig. S3). Similarly, in north-west southern America (NWS), the mean annual cycle in

253 the historical periods has, according to the reanalyses, only one distinct maximum (Fig. S3). However, the ESMs show a  
254 second maximum. We do not consider it in our analysis, but it is interesting to note that the annual cycle in this region is  
255 projected to change in the way that the temperature at this second maximum, not present in reanalyses, becomes higher than  
256 the first maximum (Fig. S4). As the (radiation-driven) annual cycle in the near-equator regions is less distinct, other climate  
257 system processes, such as the distribution of precipitation, become more important in shaping it. As a result, the shift of the  
258 temperature maximum can be indicative of a change in the occurrence of dry and wet seasons at low latitudes. At the same  
259 time, we note that in above mentioned regions with rather flat maximum and low amplitude, the ESMs and reanalyses mostly  
260 disagree on changes in amplitude, so that overall confidence in the signals is rather low.

### 261 **4.3 Annual cycle velocity**

262 Higher latitudes detect a higher magnitude of temperature velocity change than lower latitudes. For future changes, the  
263 geographical pattern of projected temperature velocity change remains the same as between the historical periods, with the  
264 magnitude of change twice as high in most of the regions (Fig. 8). The velocity change over the oceans is mostly smaller  
265 compared to the continents (Fig. 7, 8). Between the two historical periods, all regions experienced both a decrease and an  
266 increase in the slope of the annual cycle, depending on the time of year (see Fig. 7 b, c and Fig. S5). Historical changes in  
267 temperature velocity are largest in the western-central part of Euroasia (EEU, WSB, and ESB; Fig. 7). Generally, for both  
268 historical and projected changes, the regions with larger changes in velocity have a larger range between the 10th and 90th  
269 percentiles, which is expected given the definition of the diagnostic.

270 The temperature velocity changes agree between the reanalyses, except for Antarctica and the RFE (eastern Asia), and CNA  
271 (central North America) regions. Further, the ESMs tend to underestimate the reanalysis-based velocity changes in the middle  
272 and higher latitudes of the northern hemisphere, and largely agree on the smaller changes in the tropics and over the southern  
273 hemisphere. The temperature velocity changes between the two historical periods are mostly in the interval between -0.1 and  
274 +0.1 °C/day. This change of slope of the annual cycle curve can result in a temperature change of 3 °C per month. It naturally  
275 corresponds to changes in the amplitude of the annual cycle and changes in the temperature contrasts between seasons.  
276 However, Fig. S5 shows that the changes in the velocity are, in most cases, rather variable during the year, with the sign  
277 persisting not for the whole season, but rather for a week up to two months. Still, except for a couple of regions, the two  
278 reanalyses have rather similar annual cycle of temperature velocity changes in the historical periods. Unlike the temperature  
279 change, the reanalyses agree on the sign and value of annual cycle velocity change over Greenland.

280 The five ESMs mostly follow the reanalysis-based pattern of change in temperature velocity. If there is any disagreement, the  
281 models tend to underestimate the magnitude of changes. This is mainly seen in the northern hemisphere's higher latitudes.  
282 Generally, over the northern hemisphere continents, we mostly see higher fluctuation of velocity changes between negative  
283 and positive values in winter than in summer. Regarding the projections, Fig. S06 depicts a distinct annual cycle of velocity  
284 changes in the regions where the expected warming is larger in one of the seasons. A nice example is the Arctic, where we can  
285 see a decrease in velocity in the spring and the autumn, but near-zero or positive changes in winter and summer (Fig. S06).

286 This stems from projected flattening of the annual cycle and higher warming in winter than in summer. In northern mid-  
287 latitude regions, the velocity changes are more variable during winter than in summer (Fig. S06), which is connected to a  
288 higher increase of temperature in winter than in summer and shrinking amplitude, as discussed below.

#### 289 **4.4. Annual cycle amplitude**

290 Both reanalyses agree on the prevailing decrease in amplitude, with the largest changes detected in EEU (eastern Europe) and  
291 WSB (western Siberia), CNA, NWN (both northern America), the Arctic ocean, and Antarctica (Fig. 9). Unlike the temperature  
292 change, both reanalyses show that the amplitude change in the Arctic is larger than in Antarctica. The ESMs, in turn, show  
293 diverging changes of amplitude between the historical periods over the globe. Over the oceans, we see small amplitude changes  
294 with varying signs in both models and reanalyses, except for the Southern Ocean and the Arctic region, where all the models  
295 and reanalyses show an amplitude decrease (ERA5 -0.4 and CERA20C -1.1 °C in SOO, ERA5 -2.9, CERA20C -1.6 °C).  
296 Clearly, decreasing annual cycle amplitude arises from a faster increase of temperature in the colder part of the year, in  
297 comparison to the warm season (Fig. S7). Such seasonal difference in temperature trends during the 20th century has been  
298 reported by Nigam et al. (2017) for the northern hemisphere. However, there are several regions where the reanalyses show  
299 an increase in amplitude, up to 0.8 °C, e.g., Greenland, the southern part of South America, Madagascar, and interestingly also  
300 Siberia (RAR) and some regions in northern America (Fig. 9). The ESMs show decreasing amplitude everywhere. We  
301 hypothesize that the discrepancy between ESMs and reanalyses over Greenland could be connected to differences in the  
302 evolution of sea ice between simulations. A recent increase in amplitude over Greenland has also been reported by Deng and  
303 Fu (2023). Liu et al. (2024) showed an increase in the amplitude of SSTs over most of the ocean basins in recent 40 years. Our  
304 study period is longer, and the amplitude increase attributed to the anthropogenic forcings is probably masked to some extent  
305 by internal climate variability.

306 In many regions, the projected future amplitude changes have the sign opposite to the changes between the historical periods  
307 (compare Fig. 9 and 10). The largest increase is projected over the Mediterranean and West-Central Asia regions (due to  
308 summer warming being more than winter), and the largest decrease over the Arctic Ocean (due to winter warming being higher  
309 in winter than summer). Generally, the amplitude increase is projected for most of the southern hemisphere and equatorial  
310 areas, whereas most of the middle to higher latitudes of the northern hemisphere are projected to experience a decrease in the  
311 amplitude. There are a few exceptions: West-Central Europe (WCE), East-Central Asia (ECA), and the western part of the  
312 USA (WNA), where we can see an increase in the amplitude of app. 2 - 3 °C. Over the continents, the increasing amplitude  
313 indicates an increase in thermal continentality of climate, with higher contrasts between winter and summer.

314 To illustrate how the individual FDA diagnostics complement each other, the projected amplitude changes correspond very  
315 well to the projected temperature velocity changes; a higher increase in velocity is connected to a higher decrease in amplitude,  
316 and the other way around.

## 317 5. Discussion

318 The shape of the mean temperature annual cycle can be considered a very basic feature of climate. Nonetheless, we highlight  
319 large observational uncertainty related to its recent changes, i.e., distinct differences between the two reanalyses, especially  
320 over equatorial and polar regions. Multiple differences between the reanalyses might be behind the discrepancies. Besides  
321 differences in spatial resolution, CERA20C is a coupled reanalysis, whereas ERA5 was produced by the atmospheric model  
322 only. Laloyaux et al. (2018) emphasize that the former is expected to be more realistic in terms of ocean heat balance and  
323 ocean heat uptake, important for the temporal evolution of near-surface air temperature and its low-frequency variability.  
324 Regarding the discrepancies over Antarctica, the assimilated observations are scarce and might be spurious (Laloyaux et al.,  
325 2018). Moreover, the number of observations in both CERA20 and ERA5 were increasing during the study period, which  
326 might have influenced the results. In case of CERA, in which only variables measured over the ocean are assimilated, the data  
327 inputs from ships more than doubled, and data from buoys started to be assimilated after 1970 (Laloyaux et al., 2018). For  
328 ERA5, the number of assimilated observations increased from 53 000 to 570 000 between 1950 and 1970 (Bell et al., 2021).  
329 Furthermore, as pointed out by, e.g., McKinon et al. (2024), the reanalysis performance is in general questionable over regions  
330 that have spurious observations, not only in Antarctica but also over large portions of Africa or Southern America. Furthermore,  
331 Yettella and England (2018) emphasized large internal climate variability uncertainty connected to the evolution of annual  
332 cycle shape over northern hemisphere middle and high latitudes. Brunner et al. (2025) emphasize that the discrepancies  
333 between different reanalyses are rather larger in the southern ocean than in other ocean basins, not only for ERA5 and CERA20,  
334 but also for other reanalyses. Moreover, the big difference between CERA20 and ERA5 in southern high latitudes, unlike  
335 in northern high latitudes, points to the importance of the coupling between the atmosphere ocean for the southern high  
336 latitudes. As demonstrated by, e.g., Kang et al. (2023), there is a strong relationship between tropical and subtropical Pacific  
337 and temperature changes in the southern ocean, and the simulation of these features is expected to be different in ERA5  
338 (atmosphere only) than CERA (coupled simulation). The coupling does not automatically guarantee a better simulation,  
339 naturally.

340 Even though we analyze only five CMIP6 ESMs, which is admittedly a very small subset of the whole multi-model ensemble,  
341 they differ in many aspects, including spatial resolution (Table 2), model family (Merrifield et al., 2023), and climate sensitivity  
342 (Table 2, Meehl et al., 2020). It is not thus surprising that they show diverse outcomes. They are not always able to reproduce  
343 the reanalysis-based historical changes, and their projections differ in many aspects. The differences in the structure of the  
344 models imply different character of internal climate variability, which is certainly behind some of the discrepancies. ESMs  
345 with higher climate sensitivity (corresponding to higher globally averaged temperature changes as listed in Table S01)  
346 generally project larger annual cycle shape changes (e.g., CanESM5 in the Arctic, Fig. 3, 4). Even though it has been argued  
347 that the higher sensitivities are not plausible (e.g., IPCC, 2021), it is difficult to rule out the hot models, especially in the case  
348 of regional impact assessment (Palmer et al., 2023; Swaminathan et al., 2024). This is illustrated in our results by cases where

349 the regional changes in FDA diagnostics do not correspond to the differences in global mean temperature changes. For  
350 example, these cases include West Antarctica and regions in south-eastern north America.

351 Previous studies on changes in the annual cycle mostly concentrated on the amplitude and shift of the maximum. Chen et al.  
352 (2019) studied ERA-Interim-based and CMIP5-simulated spatial patterns of seasonal amplitude and phase. They concluded  
353 that the seasonal amplitude reduced during the 21st century over high latitudes of both hemispheres because cold-season air  
354 temperature increases faster than warm-season air temperature. In contrast, over low latitudes, the expected evolution is exactly  
355 the reverse. Further, the maximum of the annual cycle was projected to be delayed by 15 - 30 days over the high-latitude  
356 oceans where the sea ice is expected to shrink significantly (Chen et al., 2019). All these patterns are also obvious in our  
357 results, implying consistency between CMIP5 and CMIP6 projections. The gradual decrease of amplitude prevailing over most  
358 of the northern hemisphere has also been reported in other studies, including Stine and Huybers (2012), Wang and Dillon  
359 (2014), Nigam et al. (2017), and Cornes et al. (2018). However, we depict some regions where the reanalyses disagree on the  
360 sign of change, and also regions where both ESMs and reanalyses imply an increase in the amplitude. Delayed onset of annual  
361 cycle maximum over most of the northern-hemisphere continents was also reported by Deng and Fu (2023).

362 It is generally expected and observed that the temperature changes over land would be higher than over the ocean (e.g.,  
363 Sutton et al., 2007, see also Table S01). Our results confirm this expectation in most of cases, especially in middle latitudes,  
364 when comparing regions for large ocean basins and surrounding regions (e.g., Fig. 3, 4), and when comparing the oceanic and  
365 land parts of the marginal sea regions (e.g., Mediterranean, Caribbean, south-east Asia). Near the equator, especially in the  
366 eastern Pacific Ocean (EPO) region, the position of the annual cycle maximum is expected to change more in the future than  
367 over continental regions in South America. This is also a region with relatively high disagreement between individual models.  
368 The uncertainty is apparently connected to rather flat maximum and low amplitude of the seasonal cycle, with even a small  
369 temperature change in a part of the year potentially causing a large shift of the maximum. As already discussed, this might  
370 also be connected to changes in precipitation distribution over the seasons.

371 In a recent study, Brunner and Voigt (2024) revealed a systematic bias in the definition of percentile-based temperature  
372 extremes (Tx90p) when using too long seasonally running windows. One of the pitfalls they revealed was spurious signals of  
373 change in Tx90p, as the strength of the bias depends on the shape of the temperature annual cycle (as well as the day-to-day  
374 variability). They find two particularly affected regions: a region of increasing bias in oceans north of 45°N, except the very  
375 highest latitudes (approximately our NPO, NAO, and MED regions), and a region of decreasing bias in our ARS region (see  
376 their Fig. 5a). Connecting to our results, stronger seasonal gradients (corresponding to a higher temperature velocity) favour a  
377 stronger bias in Tx90p (Brunner and Voigt 2024). Indeed, we find a weak (in particular compared to some land regions; see  
378 Fig. 8), but clear increase in temperature velocity between 1961-1990 and 2071-2100 in all three regions affected by increasing  
379 bias (NPO, NAO, MED), which is particularly pronounced towards and away from the annual maximum (which is located  
380 around end of August/beginning of September or day of the year 240, Fig. S04). While the absolute value of the temperature  
381 velocity change is considerably higher in other regions, its systematic increase in combination with the low day-to-day  
382 temperature variability considerably contributes to the increase in Tx90p bias in these regions.

383 For the region of decreasing bias in Brunner and Voigt (2024), roughly corresponding to our ARS region, the attribution of  
384 the bias change to the temperature velocity is less clear due to a combination of two reasons; first, the decreased bias stems  
385 mainly from a very limited number of days surrounding the second annual minimum in the region (July and September; see  
386 Fig. 5c in Brunner and Voigt 2024). For CanESM5, which was used in Brunner and Voigt (2024), we do find a short consistent  
387 decrease in the temperature velocity corresponding to those months (Fig. S6). Second, the decrease in bias found in this region  
388 is also (at least partly) attributable to an increase in day-to-day variability, which is not evaluated by the FDA diagnostics.

## 389 **Conclusions**

390 This paper presented an innovative method for assessing the shape of the annual cycle. It is applicable for different climatic  
391 variables and for various purposes, with no need to make any prior assumptions about the annual cycle shape. The diagnostics  
392 we introduced provide important information about different aspects of the seasonal cycle shape and its changes: amplitude,  
393 slope, and location of extrema. We analyze annual cycles averaged over 30-year periods, but the method can also serve for  
394 analysis of shorter-term variability of seasonal cycle, to study even inter-annual variability of the shape features. Unlike  
395 methods based on monthly or seasonal means (e.g., evaluating the amplitude based on monthly values), the FDA diagnostics  
396 can capture even slight changes in the shape of the annual cycle, for example, in the timing of the maximum, discussed in  
397 Section 4.2.

398 We have illustrated the methodology on the example of the temperature annual cycle and its changes in pre-defined  
399 climatological regions. We used it to assess recent and projected changes of the temperature annual cycle in a selection of  
400 ESMs and observation-based datasets. Other potential applications include assessing other variables, for example, minimum  
401 or maximum air temperature. The changes in the shape of annual cycle of these variables can have implications for the  
402 occurrence of extreme cold or heat events. Another possibility is to apply our method for explicitly evaluating the model  
403 performance. In that case, differences between models and one or more reference datasets would be investigated. The results  
404 can be aggregated, resulting in assessments of the ensemble mean and spread. The diagnostics can be modified to evaluate not  
405 only changes between time periods, but also differences between datasets to reveal model biases in the representation of the  
406 annual cycle compared to an observational reference. If the evaluation is applied to the outputs for regional climate models or  
407 ESMs with finer resolution, the assessment can be done for smaller geographical regions, revealing more details about  
408 projected changes and their potential impacts. The definition of FDA diagnostics can thus be tailored for specific interests and  
409 applications.

## 410 **Supplement:**

411 Additional figures S01-S08. Additional table S01.

412 **Interactive computing environment**

413 Jupyter notebooks are published in Zenodo: DOI: 10.5281/zenodo.15866118

414 **Code availability**

415 Jupyter notebooks are published in Zenodo: DOI: 10.5281/zenodo.15866118

416 **Data availability**

417 Underlying CMIP6 data were downloaded from the ETH Zurich CMIP6 next generation archive (Brunner et al., 2020), but  
418 are also freely available in the ESGF. The underlying ERA5 data are freely available from the Copernicus Climate Data Store.  
419 Data from CERA20C reanalysis were downloaded from ECMWF with the help of Jan Masek from the Czech  
420 Hydrometeorological Institute. Preprocessed data used for the FDA calculations are published in Zenodo: DOI:  
421 10.5281/zenodo.15866118. For any details or requests, please contact one the corresponding authors.

422 **Author contribution**

423 EH: Conceptualization, data pre-processing, interpretation of the results, writing of the draft. LB: Conceptualization, data pre-  
424 processing, plotting, interpretation of the results. JK: Methodology development, FDA calculations, coding, and plotting. All  
425 three authors have contributed to the writing of the final text.

426 **Competing interests**

427 The authors declare no competing interests.

428 **Acknowledgements**

429 We acknowledge the CMIP community for providing the climate model data, retained and globally distributed in the  
430 framework of the ESGF.

431 We acknowledge the European Centre for Medium-Range Weather Forecasts (ECMWF) for producing the ERA5 (Hersbach  
432 et al., 2020) and CERA20C (Laloyaux et al., 2018) reanalyses.

433 We acknowledge the World Climate Research Programme's Working Group on Coupled Modelling, which is responsible for  
434 CMIP, and we thank the climate modeling groups for producing and making available their model outputs.

435 For CMIP, the US Department of Energy's Program for Climate Model Diagnosis and Intercomparison provides coordinating  
436 support and led the development of software infrastructure in partnership with the Global Organization for Earth System  
437 Science Portals.  
438 We thank the Copernicus Climate Change Service, ECMWF, and the ETH Zurich CMIP6 next generation archive (Brunner et  
439 al., 2020).  
440 Data from CERA20C reanalysis were downloaded from ECMWF with the help of Jan Masek from the Czech  
441 Hydrometeorological Institute.

#### 442 **Financial support**

443 This research was partly supported by the program of the Charles University Cooperatio "Sci-Physics". LB has received  
444 funding by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy  
445 EXC 2037 'CLICCS—Climate, Climatic Change, and Society' - Project No. 390683824, a contribution to the Center for Earth  
446 System Research and Sustainability (CEN) of the University of Hamburg. EH and JK were supported by the grant GA25-  
447 15855S of the Czech Science Foundation.

**Figure 2.** The FDA diagnostics interpretation framework. Blue and red lines illustrate an example FDA-smoothed temperature annual cycle in two time periods, except for panel (c), where the lines represent the absolute values of the 1st derivative of the FDA-smoothed curves, i.e., temperature velocity, and the dashed color lines are used to depict negative temperature velocities. (a) The black arrow corresponds to the vertical temperature change between the two periods on a specific day of the year, and the black line represents its values during the whole year. (b) Dashed lines represent the days of temperature maxima, and the black arrow corresponds to the shift of the maximum. (c) The black arrow corresponds to the change of temperature velocity between the two periods on a specific day, and the black line represents its values during the whole year. (d) The blue and red arrows correspond to the amplitudes in each period, and the vertical black arrow illustrates the change in the amplitude between the two periods.
