11 **Abstract:** Field-scale estimation of evapotranspiration (ET) using high-resolution data supports water conservation
12 and yield optimization by enabling localized water use monitoring and early detection of crop stress. This study applies
13 the Priestley–Taylor Two-Source Energy Balance (TSEB-PT) model at 15 cm resolution using unmanned aerial
14 vehicle (UAV) data over a 10-hectare field across three seasons: sugar beet (2021), potato (2022), and winter wheat
15 (2023). Key inputs included thermal infrared (TIR) for land surface temperature (LST), multispectral (MS) and LiDAR
16 data for canopy characterization, and a fusion of MS derived green area index (GAI) and LiDAR derived plant area
17 index (PAI) to derive the fraction of green LAI (f_g). Model outputs were validated against eddy covariance (EC) flux
18 data using footprint modeling. Results showed high sensitivity to LST, emphasizing the importance of accurate
19 thermal calibration. While both GAI and PAI provided comparable LAI inputs during peak growth, GAI better
20 captured functional canopy decline during stress and senescence, especially in winter wheat, where dense structure
21 led to cooling effects unrelated to transpiration. Dynamic f_g improved ET accuracy across all crops, particularly under
22 declining canopy function. Overall, TSEB-PT showed strong agreement with EC measurements (RMSE = 0.14 mm/h,
23 $R^2 = 0.49$; $R^2 = 0.81$ excluding senescence). UAV TIR based ET maps also revealed early stress signals prior to
24 changes in MS or LiDAR based metrics. This study demonstrates the value of integrating very-high-resolution UAV
25 data with the TSEB-PT model for multi-crop and season-long ET monitoring and early stress detection.

31

32 1. Introduction

33 Evapotranspiration (ET), the combined loss of water through soil evaporation and plant transpiration, is the second-
34 largest flux in the hydrological cycle after precipitation (Allen et al., 1998). ET plays a critical role in water resource
35 allocation and irrigation scheduling (Wang et al., 2014). Plant health and biomass production is closely linked to
36 transpiration, which depends on soil water availability and is regulated by stomatal and environmental conditions.
37 Accurate, timely estimation of ET at the field scale is essential for optimizing irrigation schedules, improving water
38 use efficiency (WUE) (Pereira & Pires, 2011), and supporting sustainable agriculture amid increasing water scarcity
39 and climate variability (Colaizzi, 2016).

40 Conventional ET measurement methods, such as lysimeters, sap flow sensors, and eddy covariance (EC) systems
41 (Yang et al., 2019), offer high temporal resolution but are limited in spatial coverage, making them inadequate for
42 capturing within-field variability critical to precision irrigation Yao et al., 2017). Additionally, these systems are
43 costly, making large-scale monitoring impractical (Yao et al., 2017). Satellite and airborne remote sensing approaches
44 improve spatial coverage but often lack the resolution needed for dynamic crop monitoring. Manned aircraft, while
45 capable of very-high-resolution observations, are costly and operationally demanding (Bellvert et al., 2020; Hunt Jr.
46 & Daughtry, 2018).

47 Recent advances in unmanned aerial vehicles (UAV) and lightweight, very-high-resolution uncooled thermal infrared
48 (TIR) sensors now enable on-demand, field-scale ET monitoring. UAV platforms offer both high spatial and temporal
49 resolution, allowing for detailed detection of crop water stress and rapid changes in canopy function (Niu et al., 2020).
50 TIR remote sensing in the 8–14 μm range is a key component of energy balance models, as land surface temperature
51 (LST) serves as a direct proxy for canopy transpiration and stomatal regulation if crop aerodynamics are known
52 (Tanner, 1963). Anderson et al. (2024) further reviewed the development of TIR based energy balance models, which
53 link vertical temperature gradients to sensible heat flux by modeling resistance, surface, and vegetation interactions.

54 Popular and widely used models such as SEBAL and METRIC estimate ET using TIR derived LST and LAI data
55 (Mohan et al., 2020), but their one-source energy balance formulations treat the land surface as a single layer. They
56 rely on hot/cold (not transpiring/ fully transpiring) anchor pixels to infer ET extremes, with no explicit representation
57 of soil–canopy interactions or functional canopy condition. This oversimplification can lead to inaccuracies (Niu et
58 al., 2020), especially in heterogeneous or partially senescent fields, where vegetation structure and function vary
59 spatially. However, even though these models are typically used with satellite based remote sensing, they have also
60 been applied with UAV studies (Chandel et al., 2020; Mokhtari et al., 2021; Niu et al., 2019). Some UAV based
61 studies have applied simplified alternatives such as the Deriving Atmosphere Turbulent Transport Useful To Dummies
62 Using Temperature (DATTUTDUT) (Ellsäßer et al., 2020) or the Simple Algorithm for Evapotranspiration Retrieving
63 (SAFER) (de Lima et al., 2024) but have similar constraints for very-high-resolution data at field scale.

64 Alternatively, Two-Source Energy Balance (TSEB) models partition energy fluxes between soil and vegetation, each
65 with distinct resistances (Norman et al., 1995). It is considered one of the most robust and widely used (Nieto, 2022;

66 Nassar et al., 2020) while often outperforming OSEB models like SEBAL or METRIC when compared (Guzinski et
67 al., 2020; Brenner et al., 2018; Jaafar et al., 2022; Tao et al., 2024; Xia et al., 2016) especially in variable and sparse
68 vegetation cover (García-Santos et al., 2022; Derardja et al., 2024). There are several versions but the most commonly
69 used is the Priestley-Taylor version (TSEB-PT) (Colaizzi et al., 2014). Additionally, TSEB-PT incorporates fraction
70 of green LAI (f_g) within the Priestley-Taylor formulation which allows the model to dynamically scale transpiration
71 based on the fraction of functioning canopy. This makes it especially suitable for modeling at high spatial resolution
72 with heterogeneous canopy covers from partial stress and senescence conditions. Furthermore, TSEB-PT version
73 avoids uncertainties tied to vapor pressure as opposed to the Penman–Monteith (TSEB-PM) version, which simplifies
74 deployment for UAV based applications (Colaizzi et al., 2014). The TSEB-PT model has been used with several UAV
75 crop studies including wheat (Gómez-Candón et al., 2021), Barley (Hoffmann et al., 2016); Sorghum (Tunca et al.,
76 2023a), Pomegranate (Niu et al., 2019), but with most being vineyards (Gao et al., 2021, 2023; Nassar et al., 2020,
77 2021, 2022; Nieto et al., 2019; Ortiz et al., 2019; Xia et al., 2016).

78 Recently, machine learning (ML) methods have been applied to ET estimation using multispectral, thermal, and
79 auxiliary data (Amani et al., 2023; Liyew et al., 2025). ML models often depend on large, high-quality ground data
80 such as lysimeters (Kavya and Mahadevaiah et al., 2024) or eddy covariance systems (Liu et al., 2021), resources that
81 are expensive, sparse, and highly site-specific, limiting their scalability for field-scale operational use
82 (Hirschi et al., 2017) and are time consuming (García-Santos et al., 2022). Moreover, ML models struggle to transfer
83 accurately to different locations or crop systems (Shi, 2024). In contrast, physically based models like TSEB-PT, when
84 paired with UAV-sensor inputs, offer robust, interpretable, and transferable ET estimations across different crops and
85 environments.

86 With these considerations in mind, we apply the TSEB-PT model for robust, multi-season UAV based ET estimation
87 using very-high-resolution thermal infrared (TIR), multispectral (MS), and LiDAR data. However, small-uncooled
88 TIR sensors are prone to radiometric drift and environmental noise, often requiring ground references to correct LST
89 biases (Kelly et al., 2019). Modeling canopy resistance also hinges on reliable LAI estimates. MS derived green area
90 index (GAI), which reflects pigment concentration, is widely used but susceptible to saturation in dense canopies
91 (Bukowiecki et al., 2020; Zheng & Moskal, 2009). In contrast, LiDAR is increasingly being used for crop LAI type
92 estimations (Bates et al., 2021; Hütt et al., 2022; Dreier et al., 2025). LiDAR derived plant area index (PAI) captures
93 structural canopy density and reduces saturation-related errors (Bates et al., 2021; Ma et al., 2021). The fraction of
94 green LAI (f_g), an indicator of photosynthetically active canopy, is rarely used in UAV based TSEB-PT studies. When
95 included, it is typically assumed spatially constant (Hoffmann et al., 2016) or derived from sparse ground samples (Li
96 et al., 2019) or NDVI based estimates, which lack structural depth (Nassar et al., 2022; Mendiguren et al., 2017). In
97 this study, we leverage the complementary strengths of MS (GAI) and LiDAR (PAI) to generate dynamic, spatially
98 explicit f_g estimates at pixel level. This has the potential to improved transpiration modeling that accounts for both
99 canopy structure and physiological function.

Our study expands UAV based TSEB-PT modeling across three crop types, sugar beet, potato, and winter wheat, spanning full growing seasons, with validation against EC data. Beyond validation, we evaluate how the model captures field-scale ET variability and early signals of water stress. Specifically, we assess the sensitivity of ET to thermal calibration, compare GAI and PAI as LAI inputs, and test the impact of incorporating f_g derived from MS-LiDAR fusion. By testing these components under operational UAV conditions, this work advances the use of TSEB-PT for spatially adaptive, near real-time irrigation management in precision agriculture.

2. Methods

2.1. Study area

The study was conducted at the ICOS Class 1 ecosystem site DE-RuS within the TERENO Eifel Rur observatory in Selhausen, Germany (50°51'56"N, 6°27'03"E) (<https://ddp.tereno.net/ddp/>). The 10-hectare field is situated at 101–103 m above mean sea level with the soil consisting of Pleistocene loess, Holocene translocated loess, with sand and gravel at deeper levels (Brogi et al., 2020). The western section has shallower sand and gravel deposits, creating spatial variability in crop growth, especially during water-scarce periods. Weather conditions including precipitation and air temperature, during the experiment periods can be found in the appendix (see Tab. C1 & Fig. C6).

Figure 1: The field experiment site (left) with the EC and meteorological station located in the center of the field. The different crop cover type for each year (right) with example images of plant structure and fraction of vegetation coverage over the field throughout each growing season.

The field experiment site, shown in Fig. 1, was monitored over three growing seasons with different crops each year. In 2021, sugar beet was planted from May to October, starting with 20% vegetation cover and reaching 98% by harvest. In 2022, potatoes were grown from May to August, beginning with 5% cover and closing at 87%, with ridges between rows. In 2023, winter wheat was planted from April to July, maintaining 94-98% cover, with senescence marked by visible leaf browning. Only the potato crop was irrigated, receiving three 30 mm applications in July. These crop and soil variations provide a basis to evaluate the robustness of very-high-resolution UAV data in ET models like TSEB-PT.

2.2. UAV measurements and processing

Two DJI Matrice 600 UAV were used, one carrying a LiDAR payload and the other a combined MS and TIR setup (Fig. 2). The LiDAR system included a YellowScan Surveyor with a Velodyne VLP-16 scanner and Applanix APX15 GNSS-IMU, capturing 300,000 pulses/sec at 903 nm with ~4 cm precision. Flights were conducted at 50 m altitude and 8 m/s with 50% side overlap. A Septentrio Altus NR3 GNSS base station was used for georeferencing. LiDAR data were processed using POSPac (v8.6) and YellowScan's CloudStation.

Figure 2: View of the DJI Matrice 600 UAV platforms that were used while flying over the field experiment site. (a) The M600 mounted with the YellowScan LiDAR Surveyor and DJI Zenmuse X1 RGB sensor. (b) The M600 with the FLIR Vue Pro R thermal IR modified with a ThermalCapture external heated shutter and Micasense Red-edge M multispectral sensors mounted on a 3-axis gyro system for nadir imagery.

The TIR sensor, a FLIR Vue Pro R 640 (13 mm), covered the 7.5–13.5 μm range with $\pm 5^\circ\text{C}$ accuracy and was modified with a heated shutter (ThermalCapture, AirRobot® GmbH & Co.) for improved inflight calibration. The MS sensor, a MicaSense RedEdge-M (AgEagle Aerial Systems Inc.), captured five spectral bands; red (663–673 nm) and NIR (820–860 nm) bands were used to calculate NDVI. Both sensors were mounted on a 3-axis gimbal and flown at 100 m altitude and 6 m/s, with approximately 90% image overlap. TIR calibration used internal corrections and ground temperature reference targets, while MS data were calibrated using a reflectance panel. Data from both platforms were processed in Pix4D. Flight campaign details are in the appendix (Tab. C1).

2.4. UAV data products and model implementation

TSEB-PT inputs fall into two categories: (1) surface boundary conditions derived from UAV data, including land surface temperature (LST), fractional vegetation cover (f_c), leaf area index (LAI), canopy height (h_c), and the fraction of green LAI (f_g); and (2) meteorological forcing variables, including air temperature (T_a), wind speed (u), vapor pressure (e_a), and incoming solar radiation (R_n). UAV derived variables were processed and calibrated using ground measurements, with detailed methods outlined in Sections 2.4.1–2.4.5. Data processing and raster manipulation were conducted in RStudio using the raster and lidR packages. All datasets were resampled to a common 15 cm ground sampling distance (GSD). The full UAV processing and model integration workflow is illustrated in Fig. 3.

Figure 3: Workflow of the study, showing sensor data integration and input variations used in the TSEB-PT model. The model incorporates two categories of inputs: (1) surface boundary conditions and (2) meteorological forcing variables. Key UAV derived inputs, LST (original vs. corrected), LAI (LiDAR derived PAI vs. MS derived GAI), and f_g (default = 1 vs. UAV derived), were varied across model runs to assess their impact. Section 3.2 compares ET outputs using different LST inputs; Section 3.3 evaluates the influence of LAI source and the inclusion of f_g during senescence. Final ET estimates (mm/h) are validated against eddy covariance (EC) flux measurements within the modeled EC footprint area.

2.4.1. Land surface temperature (LST) maps

To convert incoming longwave radiance from the TIR microbolometers into LST, surface emissivity values were required. Constant emissivity values were assigned to each crop type based on a literature review. Although vegetation and bare soil exhibit different emissivity values, their differences were deemed negligible for the purposes of this study. Additional radiometric calibration parameters including air temperature, relative humidity, and the distance from the sensor to the target surface were input into the FLIR Vue Pro R sensor prior to each flight.

Uncooled thermal sensors on UAV platforms, such as the FLIR Vue Pro R, are prone to radiometric instability. This is largely due to inconsistencies in the default internal non-uniformity correction (NUC) applied to the microbolometer focal plane array. To improve calibration consistency, an external heated shutter was employed. Previous studies have reported that the use of such shutters can increase temperature measurement accuracy by up to 70% (Virtue et al., 2021). Another major source of radiometric noise arises from the sensor's own temperature and its interaction with the environment. Up to fourfold of the total signal noise can be attributed to sensor self-heating (Budzier & Gerlach,

2015; Gogler et al., 2014; Sagan et al., 2019). In addition, Kelly et al. (2019) demonstrated that wind exposure can destabilize sensor readings. To mitigate these effects, the thermal sensor was housed within a custom 3D-printed enclosure designed for thermal insulation and wind shielding. Furthermore, flights were conducted at reduced speeds to minimize wind-induced variability in sensor temperature.

Once radiometric calibration and sensor stability were addressed, LST accuracy was assessed using ground based reference targets. In the 2021 field season, a hot blackbody target (metallic surface) and a cold water body were deployed, and thermal images were captured before and after each flight at 100 meters AGL (Fig. C2). Notably, Virtue et al. (2021) reported that with the use of an external heated shutter, reference targets are no longer essential throughout the entire flight but just one reference image due to improved thermal stability. A consistent temperature offset was observed. To correct for this in subsequent seasons, a multiple linear regression model was developed using the 2021 reference data. This model incorporated environmental variables (wind speed, air temperature, and humidity) to generate corrected temperature offsets. Two types of LST inputs were ultimately used in the TSEB model: (1) the original temperature (OG), based solely on the sensor's internal radiometric calibration, and (2) the target-corrected temperature (TC), which applied the offset corrections derived from reference targets and the regression model.

2.4.2. Leaf area index (LAI)

Two types of LAI inputs were used in the TSEB-PT model: multispectral (MS) based green area index (GAI) and LiDAR based plant area index (PAI). GAI is derived from spectral reflectance and represents the photosynthetically active portion of the canopy (Park et al., 2021; Wei et al., 2023), while PAI is derived from LiDAR returns and reflects the total canopy structure, essentially independent of pigment content (Bates et al., 2021). Both metrics serve as proxies for LAI, before senescence onset, due to their established relationships with leaf biophysical traits (Tan et al., 2020; Ma et al., 2021).

GAI and PAI were calculated using a modified Beer–Lambert law, a widely used approach for modeling light attenuation in plant canopies (Ali et al., 2015; Thorp et al., 2010). GAI was estimated from MS derived fractional vegetation cover (FVC) (See Eq. B1 in appendix), while PAI was derived from LiDAR based gap fraction (GF) (See Eq. B3 in appendix). A commonly used pixel based approach was used to estimate FVC (Jia et al., 2017; Yue et al., 2021; Zhang et al., 2019). NDVI was applied to differentiate vegetation amounts and soil, with thresholds determined using NDVI histograms spanning the entire growing season. GF is defined as the proportion of laser pulses reaching the ground relative to total canopy returns within each raster cell. The extinction coefficient (k) was calibrated using proven (Oguntunde et al., 2012) in-field SunScan ceptometer LAI measurements and applied inversely to solve for GAI and PAI (see Eq. B2 & B4 in appendix B). Given limited ground samples per date (four CP zones), this semi-empirical method offered a balance with the limited ground LAI samples available.

Due to known variability in k across growth stages, especially during early canopy development, 2–3 k values were assigned per growing season, as recommended by Brogi et al. (2020) and Bates et al. (2021). Adjustments were

203 typically made after the first 2–3 sampling dates when canopy architecture changed rapidly. Thereafter, k was held
204 constant through peak growth and harvest.

205 **2.4.3. Fraction of green LAI (f_g)**

206 To capitalize on the functional and structural canopy signals captured by GAI and PAI, we computed the fraction of
207 green LAI (f_g), defined as the proportion of the total canopy (PAI) that remains photosynthetically active and capable
208 of transpiring. f_g was calculated as the ratio of GAI to PAI:

$$209 \quad f_g = GAI/PAI = \left(\frac{-\log(1-FVC)}{k_{max}} \right) / \left(\frac{-\cos(\underline{\theta}) \ln(GF)}{k_{max}} \right) \quad (1)$$

210 where $\underline{\theta}$ is the LiDAR scan angle, and k_{max} is the extinction coefficient derived from peak LAI prior to senescence.
211 This formulation enables f_g to dynamically reflect changes in both pigment based canopy function and structural
212 density.

213 The f_g input was set to 1 before senescence, assuming full canopy greenness and maximum transpiration capacity.
214 After senescence onset, f_g values dropped based on relative differences between GAI and PAI, allowing the model to
215 scale transpiration potential accordingly. Senescence timing varied by crop and was identified from field observations
216 and GAI trends. For sugar beet (2021), senescence began after August 13 (three late-season dates); for potato (2022),
217 after August 3 (one senescence date); and for winter wheat (2023), senescence onset was spatially variable and
218 occurred as early as May 13, with six identified dates.

219 **2.4.4. Fractional cover (f_c)**

220 In TSEB-PT, f_c can be specified directly, however, when a LAI input is provided the model automatically computes
221 f_c via the Beer–Lambert law (see Eq. A11 in appendix). This internal derivation maintains consistency in how net
222 radiation is partitioned between soil and canopy, directly linking canopy area (whether structural or pigment-derived)
223 to modeled fluxes. From the TSEB perspective, f_c should represent physical cover (Norman et al., 1995) as it governs
224 canopy shading and soil radiation exposure which would best be based on structural LAI (PAI) as opposed to GAI.
225 Therefore, in our f_g implementation we use PAI as the LAI input to ensure f_c better reflects actual canopy geometry
226 and shading.

227 **2.4.5. Crop height (h_c)**

228 A method of difference of digital elevation models (DoD) was used to produce the h_c also commonly referred to as
229 canopy height model (CHM) (see Eq. B5 in appendix B). A flight campaign was conducted before the emergence of
230 the crops for a bare soil measurement to determine the digital terrain model (DTM_0). The remaining campaigns were
231 those with crop surface structures to derive the digital surface model (DSM_d) for that particular campaign date. Having
232 bare soil terrain data rather than using the ground points of the LiDAR for each campaign is better in decreasing

needed interpolations that would decrease the overall accuracy (Cao et al., 2019). The maximum values per pixel were taken when subtracting the DTM_0 from the DSM_d .

2.4.6 TSEB-PT model and contributions of UAV Derived Inputs

The TSEB-PT model partitions net radiation (R_n) into latent (LE), sensible (H), and ground (G) heat fluxes, with LE converted to evapotranspiration (ET, mm/h). The model was implemented using the pyTSEB library (Nieto et al., 2018). Figure 4 and Table 1 illustrate how each UAV derived variable informs distinct model components and their representation of surface–atmosphere interactions. Model equations are detailed in Eq. A1–A13 in the appendix and Norman et al., (1995).

Table 1: UAV derived model inputs, their influences within the model, and equation with which they are used.

UAV Input	Role in Model	Equation(s)
Surface temperature (T_c, T_s)	Drives partitioning and energy balance	A5, A6, A10
Fractional cover (f_c)	Radiative separation of canopy/soil temps	A10
Leaf Area Index (LAI)	Canopy resistance and transpiration estimation	A8, A11
Green LAI fraction (f_g)	Controls LE_c in Priestley–Taylor term	A11
Crop height (h_c)	Aerodynamic roughness estimation	A8, A9 (via d_0, z_0)

LST is a primary driver of H, representing the radiometric temperature of the combined canopy and soil surface. In vegetated areas, it influences aerodynamic surface temperature and temperature gradients critical for energy balance closure. LST, in conjunction with vapor pressure deficit (VPD), helps detect plant water stress, elevated LST and low transpiration under high VPD suggest stress. The f_c partitions energy fluxes between soil and vegetation. Higher f_c increases the canopy’s contribution to R_n and LE, thus generally elevating ET while reducing G and H_s .

The LAI input, MS-GAI or LiDAR-PAI in this use case, affects aerodynamic (R_a) and canopy (R_x) resistances; higher LAI (more stomata) reduces R_x enhancing transpiration and LE. The f_g input captures the proportion of active vegetation within the structural LAI. It adjusts the Priestley–Taylor coefficient (α_{PT}) to reduce LE estimates during senescence or stress, preventing overestimation of transpiration. This is especially relevant in dense and tall crops, where inner canopy cooling can be misattributed to transpiration without accurate f_g representation (Elfarkh et al., 2020; Kustas et al., 2016).

The h_c input influences R_a by determining surface roughness (z_0) and displacement height (d), key variables for modeling turbulent heat exchange with the atmosphere. Taller canopies enhance aerodynamic coupling and energy dissipation, favoring higher ET. In contrast, shorter vegetation limits this exchange, increasing sensible heat flux (H) and reducing evaporative cooling. Also, h_c indirectly affects R_x , for defining boundary-layer development and vertical wind attenuation.

Figure 4: Schematic and data illustration of UAV derived inputs used in the TSEB-PT model. The left panel shows the model architecture, highlighting the partitioning of net radiation (R_n) into latent (LE), sensible (H), and ground (G) heat fluxes, and how UAV derived variables (color coded) influence each component. Key inputs include land surface temperature (LST), leaf area index (LAI), fraction of green LAI (f_g), fractional vegetation cover (f_c), and canopy height (h_c). The right panel displays spatial maps of LST , f_c , GAI , PAI , and f_g , along with a sample transect of the LiDAR 3D point cloud used to derive h_c and PAI . Data are shown for a sugar beet field, illustrating seasonal transitions in vegetation structure and function. Together, these inputs improve spatially explicit energy balance partitioning and ET estimation, particularly under variable vegetation conditions, such as during senescence. Abbreviations: R_a (s/m): aerodynamic resistance; R_x (s/m): canopy (bulk stomatal) resistance; R_s (s/m): soil resistance; T_c (K): canopy temperature; T_s (K): soil surface temperature; u (m/s): wind speed; ea (kPa): actual vapor pressure; z_0 (m): surface roughness length; d (m): zero-plane displacement height; a_{PT} (-): Priestley-Taylor coefficient (modified here by f_g); LE_c , H_c (W/m^2): Component fluxes from canopy; LE_s , H_s (W/m^2): Component fluxes from soil.

2.4.7 Weather station, EC ET, and flux footprints validations

Ground measurements were obtained from various instruments to support UAV data validation and model calibration. EC flux data, processed according to ICOS standards, were used to validate UAV derived ET estimates. EC measurements, including wind speed, direction, and water vapor concentration, were used to compute vertical fluxes related to ET (Ghiat et al., 2021). The footprint of the EC flux station was estimated using the footprint prediction model (FPP) in RStudio (Kljun et al., 2015), which accounts for micro-meteorological conditions and surface roughness. These footprints were calculated in correspondence within the duration of each UAV flight. UAV based TSEB-PT evapotranspiration (ET) estimates were compared to eddy covariance (EC) measurements by extracting the weighted average of raster pixel values within the 90% flux footprint extent. Each flux footprint can be seen in Appendix C with Fig. C1.

3. Results

3.1. UAV data derived model inputs

283 The thermal infrared (TIR) data collected by the UAV consistently underestimated ground surface temperature when
284 compared to in-field reference targets during the 2021 season. The uncorrected TIR data showed a mean RMSE of
285 4.19 °C relative to thermometer readings but maintained strong agreement in relative temperature patterns across dates
286 ($R^2 = 0.97$). After applying corrections using ground reference targets, the seasonal RMSE improved to 2.78 °C.
287 Sensor offset (RMSE) was most strongly correlated with increased air temperature (0.74), followed by higher wind
288 speed (0.55) and denser humidity (0.34). Based on these relationships, a multiple linear regression model was
289 developed to predict and correct TIR sensor bias. This model was applied to subsequent field seasons, resulting in an
290 average increase of 2.2 °C in the LST orthomosaics to improve temporal consistency across acquisition dates. These
291 shifts in LST values before and after correction are illustrated in Fig. 5.

292
293 **Figure 5: (a) The comparison of UAV average temperatures of the ground targets as compared to the average of the**
294 **recorded temperatures of the thermometers. (b) Correlation of weather conditions with the difference (delta) between the**
295 **thermal sensor and actual temperature of ground thermal targets for each date.**

296 For LAI estimation, both multispectral derived green area index (GAI) and LiDAR derived plant area index (PAI)
297 were evaluated against ground based ceptometer LAI measurements. Across all three crops, PAI estimates were
298 consistently more accurate, with lower RMSE values and higher correlation to field observations. Specifically, PAI
299 achieved R^2 values of 0.99 for all three crops and an overall RMSE of 0.27 m²/m², whereas GAI showed greater
300 variability, especially in winter wheat, resulting in an overall RMSE of 1.02 m²/m² and R^2 of 0.88. The discrepancy
301 between GAI and PAI was most evident during senescence, when chlorophyll degradation reduced the spectral signal
302 used in GAI estimation, while LiDAR still captured high canopy structural density. These results highlight the
303 functional–structural divergence between optical and structural measurements of LAI, especially under changing
304 vegetation conditions. A comparison of GAI and PAI estimates against ground LAI measurements at the field scale is
305 shown in Fig. 6.

Figure 6: Field averaged UAV derived green area index (GAI) and plant area index (PAI) compared to ground based ceptometer LAI measurements across each campaign for three growing seasons. Ground measurements conclude prior to the onset of senescence, during which divergence between GAI and PAI becomes more pronounced due to declining pigment content in the canopy.

UAV derived canopy height (h_c) showed strong agreement with ground based measuring stick observations across all crops. In the 2023 winter wheat season, where canopy structure was most uniform, h_c estimation achieved excellent accuracy (RMSE = 0.01 m, $R^2 = 0.99$). Lower accuracy was observed in potato (RMSE = 0.12 m), likely due to the effects of ridge planting and heterogeneous canopy closure within sampled areas. Despite this, the UAV LiDAR system provided reliable height estimates across all crops, with an overall RMSE of 0.06 m and $R^2 = 0.90$. These results support the suitability of UAV based h_c for use in aerodynamic roughness parameterization within the TSEB-PT model. A comparison of UAV derived and ground measured canopy heights is shown in Fig. 7.

Figure 7: Comparison of UAV LiDAR derived canopy height (h_c) and ground based measuring stick data for each season. UAV derived values represent field wide averages, while ground measurements reflect averages within designated control point (CP) zones.

3.2. Accuracy and sensitivity of TSEB-PT ET estimates from UAV thermal corrections

To assess the impact of radiometric calibration on ET model performance, we compared TSEB-PT estimates derived from original (LST_{OG}) and target corrected (LST_{TC}) UAV thermal imagery against EC derived ET values across all three crop seasons as seen in Fig. 8.

Figure 8: Comparison of UAV derived TSEB-PT ET estimates for each season using two different TIR inputs: uncorrected original (OG) and target corrected (TC) LST data. ET outputs are compared against eddy covariance (EC) measurements within the corresponding flux footprint for each campaign.

Figure 9: RMSE and R² between modeled TSEB-PT ET and EC derived ET, averaged over the EC flux footprint. Two TSEB-PT model runs are compared based on land surface temperature (LST) input: original (OG) and target corrected (TC). Statistical metrics are presented for the entire growing season and excluding senescence periods, highlighting the influence of canopy condition on model performance.

Referring to Fig. 9, across all three crops, the use of target corrected LST (LST_{TC}) inputs reduced overall RMSE, indicating improved absolute agreement between TSEB-PT ET estimates and EC observations. For example, both sugar beet and winter wheat showed seasonal RMSE reductions of approximately 0.5 mm/h. However, while thermal correction enhanced the absolute accuracy of LST and the resulting ET values, it also introduced temporal smoothing, which in some cases reduced the model's sensitivity to short-term variability. This was most evident in the 2021 sugar beet season, where R² declined from 0.50 (LST_{OG}) to 0.32 (LST_{TC}) despite improved RMSE. Although R² decreased slightly, the improved thermal realism from corrected LST values enhances the physical accuracy of ET estimates.

In all three crop seasons, omitting campaign dates during crop senescence, showed that the model estimations performed significantly better before physiological decline of the crops. The most pronounced improvement was

observed in sugar beet, where RMSE decreased from 0.16 to 0.11 mm/h and R^2 increased from 0.32 to 0.79 when using LST_{TC} .

3.3. Accuracy and sensitivity of TSEB-PT ET estimations from different UAV based LAI inputs

Building on the thermal correction analysis, we next evaluated how the choice of LAI input, multispectral derived GAI versus LiDAR derived PAI, influences TSEB-PT ET estimates as seen in Fig 10. In addition, we used GAI/PAI to compute the fraction of green LAI (f_g), allowing dynamic scaling of the Priestley–Taylor coefficient (α_{PT}) to account for senescence or stressed vegetation. Model runs using f_g were compared to a baseline with no scaling of α_{PT} (i.e., assuming $f_g = 1$), to assess their impact on ET estimates under varying canopy conditions.

Figure 10: TSEB-PT evapotranspiration (ET) estimates were evaluated using different leaf area index (LAI) inputs: MS derived green area index (GAI), LiDAR derived plant area index (PAI), and their ratio, representing the fraction of green LAI (f_g), during periods of known senescence. UAV derived ET was compared against eddy covariance (EC) measurements within the EC flux footprint to assess model sensitivity to LAI input type. Notably, f_g scaling was introduced earlier for winter wheat in the model than the officially declared onset of senescence to account for localized early decline observed in the western portion of the field due to water deficits.

362 **Figure 11: RMSE and R^2 between TSEB-PT modeled ET and EC derived ET, averaged over the EC flux footprint. Two**
363 **different LAI inputs were evaluated: green area index (GAI) and plant area index (PAI). Statistical metrics are shown for**
364 **all campaign dates and separately for dates excluding senescence. During senescence periods, a third approach using the**
365 **fraction of green LAI ($f_g = \text{GAI}/\text{PAI}$) was also evaluated to scale transpiration according to functional canopy condition.**

366 During early to mid-season growth, when canopies were predominantly green and structurally uniform, the choice of
367 LAI input, GAI or PAI, had minimal effect on model performance. Excluding senescent dates, ET estimates from both
368 types of LAI inputs were in close agreement with EC measurements across all three crops. Coefficients of
369 determination (R^2) were also similar, with the exception of winter wheat, where GAI yielded a noticeably higher R^2
370 despite equivalent RMSE.

371 However, during senescence, discrepancies between GAI and PAI based LAI inputs became more pronounced,
372 particularly in winter wheat. While PAI values remained elevated due to the persistence of canopy structure, GAI
373 declined in response to chlorophyll degradation as seen in Fig. 6. These differences had a notable impact on model
374 accuracy over the whole growing season of winter wheat, where LAI = PAI estimates exhibited a higher
375 overestimation with a RMSE of 0.29 mm/h and lower R^2 (0.32), while LAI = GAI inputs improved performance with
376 an RMSE of 0.26 mm/h and R^2 of 0.56.

377 Incorporating f_g significantly reduced ET overestimation during senescence and improved agreement with EC
378 measurements in every season. Because of the significant and early physiological decline in winter wheat, these
379 improvements were even more significant. In winter wheat the RMSE decreased from 0.29 mm/h with LAI = PAI and
380 $f_g = 1$ to 0.17 mm/h LAI = PAI and $f_g = \text{GAI}/\text{PAI}$.

381 **3.4. Input impacts on resulting magnitude of ET map spatial variability**

382 This study revealed that TSEB-PT derived ET with very-high-resolution data varied with both magnitude and spatial
383 distribution across campaign dates influenced by the choice of UAV derived inputs. Appendix Figures B10 and B11
384 present field averaged ET values along with their standard deviations, demonstrating how input configurations affect
385 field spatial variability in modeled ET. To explore the sensitivity of ET spatial variability to input differences, we
386 analyzed the changes in the coefficient of variation (CV) of ET in response to modifications in key model inputs.
387 Specifically, Figure 12 shows how ET CV responds to the differences in input CV for LST ($\text{TIR}_{\text{OG}} \text{ CV} - \text{TIR}_{\text{TC}} \text{ CV}$),
388 LAI sources ($\text{GAI CV} - \text{PAI CV}$), and f_g ($f_g = 1 \text{ CV} - \text{GAI}/\text{PAI derived } f_g \text{ CV}$). These comparisons help establish the
389 connection between input variability and the spatial behavior of ET estimates, providing insight into which inputs
390 most strongly influence the spatial characteristics of TSEB-PT outputs across varying crop and environmental
391 conditions.

Figure 12: Comparison of average differences in the coefficient of variation (CV) between key TSEB-PT input variables (LST, LAI, f_g) and the resulting ET estimates across three crop types. This highlights how changes in the spatial variability of each input affect the spatial variability of modeled ET. The CV difference for f_g reflects the transition from a uniform value ($f_g = 1$) to a spatially variable product derived from the fusion of GAI and PAI.

Notably, with a uniform increase in average LST resulted in significant shifts in the spatial distribution of TSEB-PT ET estimates. In contrast, despite greater coefficient of variation (CV) between MS derived GAI and LiDAR derived PAI inputs, their influence on ET spatial variability was comparatively limited. The incorporation of a dynamic f_g , derived from the fusion of GAI and PAI, substantially altered the spatial representation of ET, underscoring the importance of this parameter.

Given the substantial change in ET spatial variability resulting from an essentially uniform shift in LST inputs, we further examined the corresponding ET maps for potato in early season (low vegetation cover) and late season maps (variability in vegetation state). This was to characterize the different spatial magnitudes of ET change were spatially distributed with uniform shifts in LST. These comparisons are presented in Fig. 13 where the LST_{OG} ET (lower LST and higher resulting ET) results were subtracted from those when LST_{TC} inputs were used.

Figure 13: Difference in TSEB-PT ET estimates using original land surface temperature (LST_{OG}) ET minus reference target corrected (LST_{TC}) ET. The maps illustrate how the magnitude and spatial pattern of ET differences vary depending on the dominant evaporative source (soil vs. canopy) and the presence of crop water stress.

Two key characteristics on how increased LST offset changes spatial variability in TSEB-PT ET outputs were observed. First, in early-season conditions with lower f_c , the dominant flux, whether from soil evaporation or canopy transpiration varied across dates and increased the contrast between soil and canopy with the increased temperature from LST_{TC} . Second, later in the growing season, the magnitude of ET change differed significantly depending on presence of stressed vegetation. In these cases, stressed vegetation showed a substantially larger ET reduction after LST correction. This shows thermal correction reshaped the spatial structure of modeled water use, amplifying contrasts between stressed and non-stressed zones.

3.5. Precise early identification of crop water stress with high-res ET maps

One of the most practical advantages of TIR based UAV derived ET modeling is its capacity to detect early signals of crop water stress before structural or spectral changes manifest in traditional vegetation indices. In the 2022 potato and 2023 winter wheat seasons, this capability was clearly demonstrated as seen in Fig. 14 & 15.

Figure 14: Particular dates in the potato 2022 season of Evapotranspiration (ET), green area index (GAI), plant area index (PAI) comparisons around moments of potential water related stress. ET map shows clear structures within field related

to irrigation patterns on the 3rd of August more so than with GAI and PAI. On the 29th of August, consequences in pigment and canopy structure can be seen with GAI and PAI.

Comparisons between the August 3 and August 29 UAV campaigns in 2022 revealed that, despite minimal changes in both GAI and PAI, the ET maps captured pronounced declines in water use across specific sections of the field. These reductions aligned with known zones of reduced irrigation coverage caused by limitations of the hose reel sprinkler system. Notably, areas along the northwest corner and adjacent to irrigation lanes exhibited significant ET suppression, even though they remained structurally intact in LiDAR and multispectral imagery.

A similar pattern was observed in 2023 with winter wheat, though in this case the stress was most likely attributed to known underlying soil–root interactions that have caused water stress in the past. On June 13, the ET map revealed broader and more pronounced spatial structures of suppressed transpiration that were not yet visible in the GAI or PAI maps. By June 28, however, similar spatial patterns emerged in both GAI and PAI, confirming physiological and structural canopy decline.

438 **Figure 15: Particular dates in the winter wheat 2023 season of Evapotranspiration (ET), green area index (GAI), plant area**
439 **index (PAI) comparisons around moments of potential water related stress. ET map shows clear structures within field**
440 **related to soil layer properties and root depth on the 13th of June. On the 30th of June, stress reaction in pigment and canopy**
441 **structure can be seen with GAI and PAI.**

442 **4. Discussion**

443 **4.1. Thermal accuracy and impacts on spatial ET distribution**

444 TSEB-PT's strong sensitivity to land surface temperature (LST) is well established (e.g., Hoffmann et al., 2016), but
445 this study extends those findings using very-high-resolution UAV based thermal imagery under uniform crop cover.
446 Uncorrected LST exhibited a significant underestimation, consistent with prior UAV studies (e.g., Kelly et al., 2019;
447 Han et al., 2020; Wan et al., 2024; Tunca et al., 2023b; Liu et al., 2024). This bias led to systematic ET overestimation.
448 While R^2 declined slightly after correction, the improved thermal realism enhanced physical consistency in ET
449 estimates, particularly important for cumulative ET tracking and water balance assessments.

450 Thermal bias was most severe under high air temperature and wind speed, precisely when crops face peak transpiration
451 demand and are most vulnerable to stress. This trend aligns with Sagan et al. (2019), who reported increased UAV
452 TIR underestimation under warmer conditions. In our results, stressed areas showed amplified ET deviations with
453 LST correction, indicating greater sensitivity to thermal accuracy. Underestimated LST muted ET suppression signals,
454 reducing contrast between stressed and non-stressed zones and potentially misleading irrigation responses. In addition,
455 corrected LST sharpened spatial gradients in ET by enhancing energy balance contrast, particularly under dominant
456 water or energy limitation conditions. This raised the standard deviation of ET values across the field and improved
457 spatial differentiation of stress signals.

458 Despite onboard radiometric correction and a heated shutter for non-uniformity calibration, ground based reference
459 targets remained essential for accurate LST and ET retrieval. When such targets are unavailable, alternate approaches
460 like the Dual-Temperature Difference (DTD) variant of TSEB-PT can help, though in our case, DTD yielded only
461 moderate improvements compared to ground-calibrated correction (results not shown).

462 **4.2. Implications of LAI and f_c source and sensitivity to plant physiological properties**

463 Both GAI and PAI served as effective LAI inputs for TSEB-PT during peak growth, when structural (PAI) and
464 pigment based (GAI) indicators are closely aligned, yielding similar ET estimates. This is consistent with a prior one-
465 source energy balance study showing LiDAR derived LAI can perform comparably to MS based LAI for ET
466 estimations (Wei et al., 2023). However, few studies have examined how model performance shifts under stress or
467 senescence, when canopy structure and function diverge.

468 Under these conditions, PAI remained high due to persistent canopy structure, which appears to contribute to higher
469 ET overestimation. In contrast, GAI, which reflects pigment concentration and photosynthetic activity, captured

physiological decline and produced more conservative estimations that better aligned with EC ET. This effect was most pronounced in winter wheat, where structural density persisted even as transpiration decreased. While PAI and ground based ceptometer LAI showed better agreement in absolute values, especially in dense canopies where GAI saturates, neither completely captures declining physiological function. The results may indicate that GAI (functional LAI) better reflected actual transpiration capacity, which could explain the improved model performance when it was compared to PAI with f_g held constant at 1.

The automatic derivation of f_c from LAI in pyTSEB further complicates input selection. Because f_c governs the radiation partitioning between soil and vegetation, LAI input type influences both energy distribution and canopy resistance. GAI may underestimate shading in dense or senescent canopies, leading to lower f_c and thus lower modeled ET, not only due to higher canopy resistance but also reduced radiation allocated to the vegetation component. Conversely, PAI may overstate transpiration potential in structurally intact but functionally declining canopies. It is possible that while both LAI inputs perform similarly under non-stressed conditions, GAI offers better physiological realism during stress or senescence. Future implementations could benefit from testing the decoupling of f_c and LAI inputs, using structural data (PAI) for f_c and pigment-sensitive indices (GAI) for functional canopy resistance.

4.3. Role of f_g in differentiating functional transpiration from passive cooling

Distinguishing passive canopy cooling from actual transpiration is critical in dense canopies like winter wheat, where structure remains even as physiological function declines. Unlike eddy covariance systems, which directly measure vapor flux, TSEB-PT relies on LST as a proxy. Without accounting for canopy function, models may incorrectly attribute radiative cooling to transpiration. In this study, combining LiDAR based structural LAI (PAI) and MS derived pigment-sensitive LAI (GAI) enabled the use of f_g to scale transpiration according to physiological status, improving ET agreement with EC observations, particularly during early stress and senescence.

The f_g input proved effective even before visible signs of senescence (e.g. winter wheat), detecting early transpiration suppression due to stress. Despite its value, f_g is not required in TSEB-PT and is typically omitted. Comparable scaling is also lacking in models like SEBAL and METRIC, which treat vegetation as a single layer, an approach more suited to satellite-scale applications where such structural-functional distinctions are impractical. UAV platforms, however, not only offer the spatial resolution needed, but also provide new sensing capabilities, such as 3D structural mapping from LiDAR, that facilitate the integration of inputs like f_g .

UAV based ET studies that exclude the use of f_g in their TSEB-PT implementation further supports the importance of its inclusion. Gómez-Candón et al. (2021) reported overestimated ET (RMSE = 0.24 mm/h) in wheat without using f_g . This overestimation is more apparent in the later season with senescence. This overestimation is nearly identical to ours for winter wheat when we also excluded f_g . Similarly, Tunca et al. (2023a) observed overestimation in stressed sorghum and proposed manually adjusting the Priestley–Taylor coefficient (α), while our results show that incorporating f_g offers a more targeted and spatially dynamic alternative. Bozorgi et al. (2024) also identified

503 inaccurate assumptions about green canopy fraction as a source of TSEB bias, reinforcing the importance of function
504 based scaling.

505 As shown in Figure 12, f_g influenced spatial ET variability more strongly than LAI type alone, highlighting its
506 importance for accurate measurement. In winter wheat, this influence was limited, likely due to LAI saturation (>6),
507 where additional canopy does not meaningfully alter radiation interception through f_c . In contrast, sugar beet and
508 potato, with lower canopy density, showed greater f_g sensitivity. Given the strong link between f_c and f_g , improving f_c
509 parameterization beyond the fixed extinction coefficient of the Beer–Lambert law used within the model could be
510 valuable.

511 UAV LiDAR methods can now provide purely structural, high-resolution f_g estimates, avoiding pigment-related biases
512 inherent in reflectance-only approaches (Chirouze et al., 2014). Unlike maximum NDVI methods, which fail to
513 account for structural leaf loss during senescence, LiDAR derived f_g can explicitly track the green fraction relative to
514 total canopy volume, potentially reducing biases in ET partitioning. These capabilities should be more widely
515 integrated into UAV-based TSEB-PT workflows.

516 **4.4 Future considerations with UAV TSEB model implementation**

517 Satellite-based ET models have traditionally operated at coarse spatial scales, assuming simplified canopy structure
518 and uniform land cover. In nearly all TSEB-PT applications, the LAI input is based on green LAI or GAI (Chirouze
519 et al., 2014). Because f_c is often derived from LAI via the Beer–Lambert law in TSEB-PT (e.g. current pyTSEB), this
520 can bias flux estimates in stressed or senescent crops by excluding nonfunctioning foliage that still shades the soil,
521 leading to overestimation of soil heat flux (G) and soil-related flux components (Chirouze et al., 2014). While some
522 studies have used plant area index (PAI) for f_c (Guzinski et al., 2014; Guzinski et al., 2020), these are rarely derived
523 from purely structural metrics. As noted by Chirouze et al. (2014), f_c should reflect total canopy structure, whereas
524 LAI should represent only the photosynthetically active portion. UAVs now enable direct, high-resolution
525 measurements of both canopy structure and function. Leveraging structural LiDAR derived PAI for f_c (radiation
526 partitioning) and functional multispectral derived GAI for LAI (canopy resistance) could enhance physiological
527 realism in partitioning latent (LE_c) and sensible (H_c) heat fluxes, and warrants targeted testing.

528 Further sensor innovations could enhance the parameterization of ET models. For example, more detailed structural
529 information from the entire canopy could be used to derive multi-layer GF profiles (Bates et al., 2022), supporting
530 improved estimates of structural LAI. Additionally, LiDAR intensity, typically operating in the NIR range (Kim et
531 al., 2009), has shown physiological associations with crop LAI (Hütt et al., 2022) and biomass (Montzka et al., 2023),
532 offering potential as a dual-use input that integrates both structural and functional canopy traits into LAI and f_g
533 estimates. UAV LiDAR can also contribute to guiding the parameterization of surface roughness as adjustments made
534 to soil resistance coefficients has shown to be important (Li et al., 2019). Moreover, UAV-mounted radar systems,
535 including synthetic aperture radar (SAR) and ground-penetrating radar (GPR), may provide novel pathways for
536 assessing canopy or surface moisture conditions (Wu & Lambot et al., 2022), which are critical for accurate energy

537 flux partitioning. By leveraging the spatial precision and 3D reconstruction capabilities of UAV platforms, future
538 research can further refine ET model inputs and improve accuracy across structurally complex and heterogeneous
539 crop environments.

540 **4.5. Practical impacts and considerations for farming practices**

541 Physically based models like TSEB-PT offer major advantages over empirical or ML methods by simulating land–
542 atmosphere energy exchanges without requiring extensive training data. In this study, TSEB-PT achieved accurate ET
543 estimates using minimal ground measurements, just four control plots for LAI and h_c calibration and two thermal
544 reference targets early in the season. Even fewer control points may suffice, shifting greater importance to UAV sensor
545 quality and data type (e.g., LiDAR vs. MS). This highlights the operational value of TSEB-PT when paired with UAV
546 platforms that can resolve fine-scale canopy and surface variability not captured by satellites.

547 The spatial and temporal resolution of UAVs allows ET to be mapped at actionable scales. In this study, UAV TIR-
548 based ET estimations with TSEB-PT detected early signs of crop stress before they were visible in conventional means
549 with MS or LiDAR based metrics. This capability enables the possibility of targeted, timely irrigation interventions.
550 For instance, in the potato field, ET maps revealed under-irrigated zones just days after a hose reel event. In winter
551 wheat, suppressed ET matched shallow gravel layers, flagging naturally water-limited zones that experienced early
552 senescence. Such spatial detail would be difficult to detect through scouting or coarse-resolution remote sensing but
553 is vital for optimizing yield and water use efficiency.

554 ET maps derived from UAV and TSEB can be interpolated to daily totals and integrated with rainfall and irrigation
555 data to calculate crop water deficits or surpluses, supporting more precise irrigation scheduling. Several interpolation
556 methods for converting instantaneous ET to daily values merit further investigation, particularly in relation to thermal
557 sensor bias propagation, optimal overpass timing, and capturing the diurnal ET cycle through high-temporal UAV
558 data. While this study focused on single-time observations aligned with EC fluxes, it highlights the potential of very-
559 high-resolution UAV data and emerging sensor technologies to enhance spatial ET accuracy and inform future
560 methodological advances.

561 **5. Conclusion**

562 This study demonstrates the effectiveness of integrating very-high-resolution UAV multi-sensor data with the TSEB-
563 PT model for accurate, field-scale ET estimation across sugar beet, potato, and winter wheat over full growing seasons.
564 With minimal ground calibration of UAV inputs, the model showed strong agreement with EC measurements,
565 confirming its potential for operational use in precision irrigation and water management.

566 Among UAV derived inputs, TIR data was both the most influential and the most error-prone. Uncooled TIR sensors
567 systematically underestimated LST under high-temperature and high-VPD conditions, leading to ET overestimation.
568 Absolute LST correction using ground reference targets significantly improved both ET magnitude and spatial
569 contrast, emphasizing the need for accurate thermal data. Vegetation inputs were also critical. While LiDAR derived

PAI and MS derived GAI performed similarly as LAI inputs for TSEB-PT during peak growth, results showed GAI more effectively reflected functional canopy decline under stress and senescence which may lead to a more accurate ET estimation during such periods. To further improve physiological relevance, we provided a dynamic input for f_g , derived from LiDAR-MS fusion with a GAI:PAI ratio. This enhanced ET accuracy and spatial variability, particularly in dense or senescing canopies, and proved valuable even before official senescence periods or visible signs of stress. Its inclusion could address overestimation issues seen in previous UAV based studies that omitted a functional canopy scaling parameter.

UAV platforms offer advantages over satellite systems by enabling fine-scale reconstruction of canopy structure using 3D LiDAR, along with thermal and spectral sensing for precise boundary layer characterization. These tools open new opportunities for near real-time ET mapping and water use assessment at actionable scales.

Key contributions of this study include:

- Demonstrating the robustness of TSEB-PT with UAV inputs and minimal ground calibration.
- Underscoring the importance of accurate TIR calibration, especially during heat stress.
- Clarifying divergence between structural (PAI) and functional (GAI) LAI inputs under stress.
- Proposing a LiDAR-MS fusion approach to estimate f_g for dynamic transpiration scaling.
- Establishing the value of f_g in TSEB-PT to improve ET accuracy across varying physiological states.
- Identifying crop-specific modeling challenges, especially in dense canopies like winter wheat.
- Showing the potential of UAV TIR based ET mapping to detect early stress to guide targeted irrigation.

Ultimately, this study highlights the value of combining UAV sensing with physically based models such as TSEB-PT for reliable, very-high-resolution ET monitoring. Future work should further explore the decoupling and type of inputs for f_c and LAI from advancing UAV sensors. In addition, further testing and improving dynamic LiDAR-MS based f_g integration across diverse cropping systems to enhance physiological realism and model scalability.

Appendix A: Description of the TSEB-PT model implementation

The Two-Source Energy Balance model with Priestley-Taylor formulation (TSEB-PT; Norman et al., 1995) was used to estimate surface energy fluxes, particularly latent heat flux (LE), by partitioning soil and canopy contributions based on radiometric surface temperature. The model was implemented in Python using the open-source pyTSEB package (Nieto et al., 2018). For more detailed description of TSEB, please refer to Norman et al. (1995) and W. P. Kustas & Norman (1999).

A1. Energy balance equations

$$R_n = LE + H + G \quad (A1)$$

Fluxes are partitioned into canopy and soil components:

601 $R_{nc} = H_c + LE_c$ (A2)

602 $R_{ns} = H_s + LE_s + G$ (A3)

603 Soil heat flux GGG is parameterized as a fraction of R_{ns} :

604 $G = c_g R_{ns}$ (A4)

605 Where $c_g=0.35$ is an empirical constant (Choudhury et al., 1987; Kustas & Daughtry, 1990).

606 **A2. Sensible heat partitioning and air temperature**

607 The total sensible heat flux H is calculated as:

608 $H = H_c + H_s = \rho C_p \left[\frac{T_{ac} - T_c}{R_a} \right] = \rho C_p \left[\frac{T_c - T_{ac}}{R_x} + \frac{T_s - T_{ac}}{R_s} \right]$ (A5)

609 Where T_{ac} = within-canopy air temperature (Kelvin); T_c and T_s = canopy and soil surface temperature components
610 derived from UAV thermal imagery; ρ = air density (kg m^{-3}); C_p = heat capacity of the air at constant pressure (J/kg/
611 K); R_a , R_s , and R_x = aerodynamic resistances (s m^{-1}).

612 The in-canopy air temperature is:

613 $T_{AC} = \frac{\frac{T_A}{R_a} + \frac{T_c}{R_x} + \frac{T_s}{R_s}}{\frac{1}{R_a} + \frac{1}{R_x} + \frac{1}{R_s}}$ (A6)

614 **A3. Resistance parameterizations**

615 Soil boundary layer resistance (Kustas & Norman, 1999):

616 $R_s = \frac{1}{c(T_s - T_A)^{\frac{1}{3}} + b u_s}$ (A7)

617 With the semi-empirical constants, b and c left at their default values. u_{su} represents wind speed near the soil surface.

618 Canopy resistance (Norman et al., 1995):

619 $R_x = \frac{C'}{LAI} \left(\frac{S}{u_{d_0} + z_{0m}} \right)^{\frac{1}{2}}$ (A8)

620 Where $C'(\text{s}^{1/2} \text{ m}^{-1}) = 90 \text{ s}^{1/2} \text{ m}^{-1}$; LAI = leaf area index estimated from either UAV multispectral GAI or LiDAR PAI;
621 S (m) = characteristic leaf size; $u_{d_0} + z_{0m}$ is the wind speed at the height reference height; $d_0 + z_{0m}$ as d_0 is the zero-
622 plane displacement height and z_{0m} is the roughness length for moment estimated from UAV derived crop height.

$$R_a = \frac{\ln\left(\frac{z_T - d_0}{z_{0H}}\right) - \psi_h\left(\frac{z_T - d_0}{L}\right) + \psi_h\left(\frac{z_{0H}}{L}\right)}{k' u_*} \quad (\text{A9})$$

z_T is the measurement heights for wind speed u (ms^{-1}). d_0 is the zero-plane displacement height, z_{0H} is the roughness length for momentum and heat transport with $z_{0H} = z_{0m} (-k_B - 1)$. The ψ (ζ) terms in Eqs. 7a and are the adiabatic correction factors for momentum. L being the Monin–Obukhov length (m).

A4. Radiometric temperature decomposition

The observed directional radiometric temperature T_{RAD} is decomposed as:

$$T_{\text{RAD}}(\theta) = [f_c(\theta)T_c^4 + (1 - f_c(\theta))T_s^4]^{1/4} \quad (\text{A10})$$

Where $f_c(\theta)$ = vegetation fractional from the viewing angle (θ) calculated from UAV based multispectral.

A5. Priestley-Taylor approach to canopy transpiration

The initial estimate of LE_c uses the Priestley-Taylor formulation:

$$LE_c = \alpha_{PT} f_g \frac{\Delta}{\Delta + \gamma} R_{nc} \quad (\text{A11})$$

Where $\alpha_{PT} = 1.26$ (iteratively reduced if needed to achieve plausible solution $LE_s > 0$; see W. Kustas & Anderson (2009)); f_g = fraction of green LAI derived from UAV based hybrid combination of multispectral and LiDAR data; Δ = slope of saturation vapor pressure curve (kPa K^{-1}); γ = psychrometric constant (kPa K^{-1}).

$$f_c(\theta) = 1 - \exp[-k_{be}(\theta)LAI] \quad (\text{A12})$$

with k_{be} being the extension coefficient of canopy with a leaf angle distribution defined by the Campbell (1990) parameter.

$$k_{be} = \frac{\sqrt{\chi^2 + \tan^2 \theta}}{\chi + 1.774 (\chi + 1.182)^{-0.733}} \quad (\text{A13})$$

Appendix B: Sensor derived metrics

B1. Green area index (multispectral)

$$FVC = \frac{NDVI - NDVI_s}{NDVI_v - NDVI_s} \quad (\text{B1})$$

with $NDVI_s$ being the upper threshold for NDVI values representing soil pixels and $NDVI_v$ representing the upper threshold of healthy vegetation.

$$GAI = \frac{-\log(1 - FVC)}{k(\theta)} \quad (\text{B2})$$

648 $k(\theta)$ = extinction coefficient, parametrized using SunScan ceptometer LAI measurements. k was adjusted once
649 between early and mid-late season and then held constant through senescence.

650 B2. Plant area index (LiDAR)

$$651 \quad GF = \frac{n_{ground}}{n} \quad (B3)$$

652 n_{ground} = number of LiDAR returns classified as ground. n = total number of returns (ground + vegetation) in the
653 pixel.

$$654 \quad PAI = -\frac{\cos(\theta) \ln(GF)}{k} \quad (B4)$$

655 θ = LiDAR scan angle ; GF = gap fraction from previous equation; k = extinction coefficient (same as above),
656 adjusted once mid-season and then held constant.

657 B2. Crop height (LiDAR)

$$658 \quad h_c = DSM_d - DTM_0 \quad (B5)$$

659 DSM_d = digital surface model from the crop canopy (per flight date); DTM_0 = digital terrain model from the bare soil
660 pre-emergence flight.

661 Appendix C: Supplemental material

Figure C1: The estimated EC footprints for each TIR campaign flight time interval to be used to compare the TSEB-PT ET values within this spatial extent to the EC ET estimations.

Figure C2 (a.) ground photo and aerial TIR view of the hot and cold temperature ground reference targets (b.)

669 pre-correction and post-correction graphed RMSE of TIR images in the 2021 season (c.) correlation of weather
670 factors with RMSE.
