Abstract. The Joint Aeolus Tropical Atlantic Campaign (JATAC) conducted 2022 in Cabo Verde has provided quantitative lidar measurements, in particular from the NASA Langley High Altitude Lidar Observatory (HALO) on-board DC-8 aircraft, for process level understanding of tropical dynamics, as well as for satellite validation. For the first time, optical properties of particles (i.e., backscatter, extinction, attenuated backscatter coefficients, and depolarization ratios) have been measured for extended tropospheric sections collocated with the Aeolus satellite overpasses with limited geolocation and time offsets. This has contributed to the evaluation of the Aeolus Level-2A (L2A) aerosol optical properties product. In addition, localized aerosol profiles were measured by the ground-based multiwavelength Raman polarization and water-vapor lidar Polly^{XT}.

With this study, we assess the quality of the Aeolus L2A product retrieved with the Standard Correct Algorithm (SCA) and the Maximum Likelihood Estimation (MLE) as part of the September 2022 dataset reprocessed with the L2A processor version 16. The focus is given to the 355 nm aerosol retrievals given at finer horizontal resolution, i.e., so-called Aeolus measurement level of ≈ 18 km. They are compared to the 532 nm HALO airborne profiles that are converted to 355 nm using the backscatter Ångström exponent. HALO and Polly^{XT} polarization lidars also provide insights about the L2A algorithms limitations when looking at non-spherical particles such as Saharan dust. Even though having no cross-polarized component the Aeolus measurements can be corrected using collocated observations with such instruments that include both co-polarized and cross-polarized components of the backscattered light. Moreover the cross validation with independent lidar measurements enables to estimate lower limits for Aeolus backscatter detection.

1 Introduction

The Aeolus Level-2A (L2A) Aerosol Optical Properties Product (Flament et al., 2021) processed from the first UltraViolet (UV) Doppler lidar in space ALADIN (Atmospheric LAsER Doppler INstrument) has been gradually improved since its first implementation following the launch of the mission in 2018. Initially referred to as a spin-off product the validity of its independent retrieval of the extinction and backscatter coefficients for particles (Ansmann et al., 2009; Flamant et al., 2008) was demonstrated using independent datasets for validation (Abril-Gago et al., 2022; Gkikas et al., 2023) and scientific applications (Baars et al., 2021; Khaykin et al., 2022).

In particular, the use of aerosol retrievals from the so-called Standard Correct Algorithm (SCA) developed at Institut Pierre Simon Laplace (IPSL) and Meteo France, revealed limitations (Baars et al., 2020). This first algorithm corresponds to a direct inversion of the lidar equations without a-priori conditions and is highly affected by the noise (Flament et al., 2021). The primary mission of Aeolus was to measure vertical profiles of the Earth's winds at the global scale, from the surface up to the lower stratosphere. The vertical range bins are limited to 24 and from 250 m to 2 km thickness, and reaching from the ground to a maximum of 30 km altitude. The first objective was to focus on aerosol-free regions of the atmosphere with atmospheric signal by molecules from the Rayleigh channel. Because of the attenuation of the laser beam due to the overlying molecular atmosphere the Signal-to-Noise Ratio (SNR) decreases with altitude decrease, with the smaller values corresponding to the lowest range bins.

Every version of the L2A processor was coming typically every six months during the operational phase of the Aeolus mission. Together with the technical documentation, each processor version forms a L2A product level labelled as Baseline. A new algorithm was developed using physically constrained optimal estimation to compensate the noisy signals, especially when deriving the extinction coefficients. This new algorithm, called Maximum Likelihood Estimation (MLE) (Ehlers et al., 2022), was implemented through L2A processor labelled Baseline 15 by September 2022. The MLE was initially processed on the coarser Aeolus horizontal resolution, i.e., referred as Basic Repeat Cycle (BRC) or observation, and resulting from a signal accumulation over ≈ 90 km, to be aligned with the SCA algorithm. Later, it was decided to provide the MLE at a sub-BRC level with higher horizontal resolution of ≈ 18 km. These retrievals are labelled MLEsub within the L2A product Baseline 16. The L2A algorithms SCA and MLE were maintained and improved at Meteo France until Baseline 15, the activities being transferred to the Leibniz Institute for Tropospheric Research (TROPOS) by Baseline 16.

The Aeolus dataset corresponding to the 2022 Joint Atlantic Tropical Campaign (JATAC) have been processed with Baseline 16 as part of the 4th reprocessing campaign activities conducted by the Aeolus Data, Innovation and Science Cluster (DISC). A summary of quality of Aeolus data products can be downloaded at <https://earth.esa.int/eogateway/documents/d/earth-online/aeolus-summary-reprocessing-4-fm-b-disc-2024-04-30>. The reprocessed dataset enables to assess the performance of both SCA and newly implemented MLEsub algorithms using independent lidar measurements. The present study focuses on cross sections of the atmosphere up to ≈ 10 km altitude observed by the High Altitude Lidar Observatory (HALO) (Carroll et al., 2022; Nehrir et al., 2018) onboard NASA's DC-8 remote sensing aircraft (Bedka et al., 2021; Nehrir et al., 2017) flying towards north and collocated with Aeolus ascending overpasses above the East Atlantic ocean. The small geolocation offset (i.e., less

than 6 km) and time offset (i.e., less than an hour) between DC-8 flights and Aeolus offer a unique opportunity to compare both Aeolus ALADIN and DC-8 HALO continuous measurements of aerosol optical properties with very close collocation. In addition, direct profiles above Mindelo, Cabo Verde are selected to be compared with aerosol retrievals from ground-based multiwavelength Raman polarization and water-vapor lidar Polly^{XT} (Baars et al., 2016; Engelmann et al., 2016). Combining measurement from satellite, aircraft-based and ground-based instruments enables to get a complete picture of tropospheric aerosols. Independent retrievals of aerosol depolarization ratio provided by HALO and Polly^{XT} also help to understand how the cross-polarized component of the light missed by Aeolus impacts the L2A aerosol retrievals (Gkikas et al., 2023). The Cabo Verde region is indeed known to be affected by highly depolarizing particles such as Saharan dust (Haarig et al., 2022; Rittmeister et al., 2017). The HALO and Polly^{XT} observations will support further refinement of Aeolus products and may complement the classification database for dominant aerosol type.

The Aeolus mission was part of the ESA Earth-Observation Programme as a demonstrator for wind lidar technology. In addition to the proof of concept for a first UV Doppler lidar in space (Dabas et al., 2008), the mission objectives include the evaluation of the high spectral resolution (HSR) capacity of the ALADIN instrument. Aeolus is indeed able to separate the contributions from molecules and particles contrary to elastic backscatter lidars such as CALIOP aboard NASA/CNES CALIPSO (Winker et al., 2009). This results in no ambiguities in aerosol and cloud optical properties, and no requirements for a-priori hypothesis on extinction-to-backscatter ratio, i.e., so-called lidar ratio. A key advantage of the Aeolus measurement is also the simultaneous aerosol and wind lidar profiling. The cross-comparison of Aeolus L2A data with independent aerosol retrievals are anticipating the next missions such as EarthCARE (Illingworth et al., 2015) and Aeolus-2. Moreover, the quality assessment of Aeolus aerosol product has been mainly achieved with localized ground-based measurement (Abril-Gago et al., 2022; Gkikas et al., 2023; Paschou et al., 2022) during the operational phase until successful re-entry in the earth atmosphere during summer 2023. The present study offers a unique opportunity to analyse longer atmospheric sections up to 626 km long collocated with aircraft observation in various atmospheric conditions.

In this paper the Aeolus L2A algorithms SCA and MLE and the JATAC campaign are introduced. Then, the NASA HALO lidar observations performed during the Convective Processes Experiment - Cabo Verde (CPEX-CV) airborne field campaign (Nowottnick et al., 2024) are presented. The wavelength conversion of the HALO measurements and re-gridding to match Aeolus sampling is described followed by a results section firstly showing direct profiles above Mindelo, Cabo Verde observed by Aeolus and HALO with ground-based lidar Polly^{XT}. Then the cross-comparison of the tropospheric sections between Aeolus and re-gridded HALO is described. A conclusion section is enclosing the paper, summarizing the L2A algorithm performance and sharing recommendations for future applications. This will be appreciated by the atmospheric science community as Aeolus data are gradually disseminated to public since 2021, encouraging scientific studies using the dataset.

2 Lidar measurements above the Atlantic in context of the Aeolus Tropical Campaign 2022

2.1 Aeolus L2A aerosol product: SCA and MLE algorithms concept

The present paper focuses on Aeolus L2A aerosol and clouds optical properties product retrieved with the SCA and MLE algorithms.

85 **Standard Correct Algorithm.** The SCA algorithm corresponds to a direct inversion of the lidar equations from the accumulated Rayleigh and Mie signals as measured by Aeolus. Making use of the HSR capacity of ALADIN the attenuated backscatter coefficients for molecules $\beta_{\text{mol}}^{\text{att}}$ and particles $\beta_{\text{part}}^{\text{att}}$ are resulting of cross-talk correction of the lidar signals from vertical matching between Rayleigh and Mie channels, i.e., calculated from the backscattered signal and the transmission through the atmosphere split up in molecules and particles contributions as described in Eqs. (7) and (8) of Flament et al. (2021). The
90 particulate backscatter β_{part} and extinction α_{part} are derived from the cross-talk corrected products and the molecular backscatter β_{mol} is related to air density, as shown with Eqs. (9), (10) and (14) of Flament et al. (2021). The particulate backscatter β_{part} and extinction α_{part} are measured independently without a-priori conditions (Flamant et al., 2008). The range bins are considered homogeneously populated by particles and the top bin is assumed to contain no aerosol.

Maximum Likelihood Estimation. As the SCA is sensitive to noise, leading to non-physical retrievals in low SNR regions,
95 a new approach based on optimal estimation was introduced in the L2A processing by Baseline 15. It is referred to as Maximum Likelihood Estimation (MLE) and consists in a reverse processing with derivation of optical parameters, i.e., the physically modeled state that agree the most with real signals as illustrated in Eq. (11) of Ehlers et al. (2022). The MLE approach makes use of the limited memory quasi-Newton L-BFGS-B algorithm (Zhu et al., 1997). Contrary to the SCA it is a constrained processing with physical limits assuming vertical collocation between the extinction and the backscatter. The lidar ratio for
100 particles can't exceed a range from 2 sr to 200 sr and the extinction coefficient must be positive (Ehlers et al., 2022).

The Aeolus L2A product includes aerosol retrievals from multiple algorithms and varying horizontal resolutions. The SCA coarser sampling is the observation level referred as BRC of ≈ 90 km horizontal. It corresponds to a signal accumulation of 600 consecutive laser pulses. The so-called « measurements » are the data element resulting from the accumulation of less pulses, comprised in sub-BRC profiles up to 30. On September 2022, the settings are the following: 5 consecutive measurements of
105 ≈ 18 km correspond to 1 BRC of ≈ 90 km. The SCA particulate and molecular attenuated backscatters are aligned with the measurement level and the other SCA products (e.g., extinction and backscatter coefficients for particles) are aligned with the BRC level. The BRC level products are affected by uncertainties as the averaging may encompass signal from different conditions (e.g., broken clouds and non-homogeneous aerosol layer).

The aerosol retrievals derived with the MLE algorithm were initially aligned with the BRC level. The L2A development
110 team decided to provide the MLE at finer horizontal resolution sub-BRC, i.e., measurement level by Baseline 16. The JATAC 2022 then enables to assess both SCA and MLEsub products aligned with this sub-BRC resolution. Figure 1 illustrates the difference between an Aeolus BRC and the sub-BRC sampling: the ground track for one BRC of ≈ 90 km is shown in Fig. 1a (green) and the five corresponding sub-BRC measurements of ≈ 18 km are illustrated in Fig. 1b.

The L2A products selected for the study are the SCA particulate attenuated backscatter coefficient $\beta_{\text{part}}^{\text{att}}$, the MLEsub backscatter coefficient for particles β_{part} , and the MLEsub extinction coefficient for particles α_{part} . The Quality Check (QC) flags provided for MLEsub retrievals have been applied. They are based on SNR and error estimates thresholds described in details in the L2A user guide version 2.2 (Traon et al., 2022). It must be noted that the Baseline 16 does not include QC flags for SCA particulate attenuated backscatter which then contains non-physical values (i.e., negative up to 40 %) because of non-perfect cross-talk correction. The negative values are distributed in low SNR regions with aerosol-free conditions. It was decided to flag the negative values for the study.

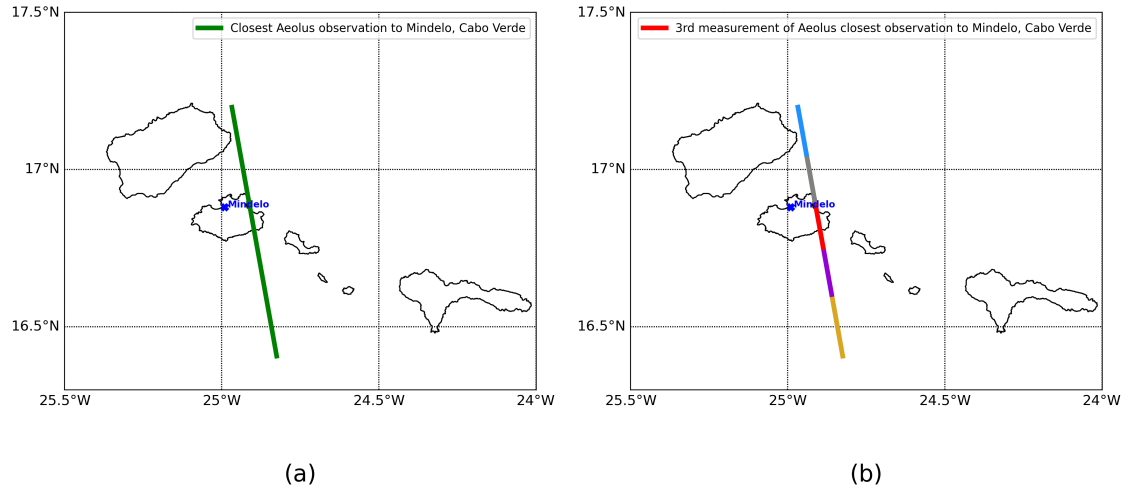

Figure 1. Illustration of Aeolus coarser horizontal sampling BRC (observation of ≈ 90 km) (a) and corresponding sub-BRC profiles (measurement of ≈ 18 km) (b) on 16 September 2022.

2.2 The Joint Aeolus Tropical Atlantic Campaign JATAC

JATAC was instigated by the European Space Agency (ESA) in Cabo Verde from June to September of 2021 and 2022. It aimed at providing reference atmospheric measurements to validate ESA Aeolus wind and aerosol products retrieved at 355 nm, and prepare upcoming ESA Earth Explorer missions such as EarthCARE (Illingworth et al., 2015). The JATAC also addressed scientific objectives regarding long-range transport of Saharan dust particles, e.g., investigating their relation to the formation of convective systems and improve climate and numerical weather prediction models (Fehr et al., 2023; Flamant et al., 2024). The science objectives were covered through simultaneous observations of multiple aircraft collocated with Aeolus overpasses and ground-based cloud and aerosol measurement, including radiosondes and dropsondes. The ground-based instruments were operated at Ocean Science Center Mindelo, Cabo Verde in 2021 and 2022. This includes the multiwavelength Raman polarization and water-vapor lidar Polly^{XT} (Baars et al., 2016; Engelmann et al., 2016), the eVe reference polarisation lidar (Paschou et al.,

2022), and a W-band Doppler cloud radar. The Airborne Demonstrator for the Direct-Detection Doppler Wind Lidar ALADIN (Lemmerz et al., 2023) onboard DLR Falcon-20 aircraft was deployed in September 2021 such as the high-spectral-resolution Doppler lidar (LNG) (Bruneau et al., 2015) onboard Safire Falcon-20 aircraft. The Aerovizija Advantic WT-10 light aircraft with optical particle spectrometers, filter-photometers and nephelometers for in-situ aerosol characterisation was deployed in 135 2021, and operated during two weeks in September 2022 (Fehr et al., 2023).

3 NASA’s Convective Processes Experiment – Cabo Verde (CPEX-CV)

3.1 NASA DC-8 aircraft and flights above Cabo Verde

NASA CPEX-CV (Nowottnick et al., 2024; Zawislak and Zipset, 2023) is a continuation of the CPEX (Turk et al., 2020) and CPEX — Aerosol & Winds (CPEX-AW) (<https://asdc.larc.nasa.gov/project/CPEX-AW>, <https://www.earthdata.nasa.gov/data/projects/cpex-aw>) campaigns, both conducted in the tropical East Atlantic in 2017 and 2021, respectively. One key objective was to study the atmosphere dynamics in order to interpret space-borne remote measurement of tropospheric aerosols as part of JATAC 2022. CPEX-CV consisted of the deployment of NASA’s DC-8 aircraft out of Sal Island, Cabo Verde during summer of 2022. 140

Some flights of the DC-8 have been specifically designed to include a collocated section with the Aeolus overpasses. Figure 2 illustrates the Aeolus orbits ground track for September 2022, the NASA DC-8 aircraft flying below the satellite in the same direction toward North for the ascending overpasses only (i.e., Fig. 2 : green (a), rose (b)). Three scenes up to 626 km long are presented in this study and correspond to 09 September 2022, 15 September 2022, and 16 September 2022. The scenes 09 September 2022 and 16 September 2022 correspond to Friday ascending overpasses (Fig. 2b, rose) with closest profile to Mindelo, Cabo Verde at $\approx 19:33$ UTC. The scene 15 September 2022 corresponds to Thursday ascending overpass (Fig. 2a, 150 green) with closest profile to Mindelo, Cabo Verde at $\approx 19:20$ UTC.

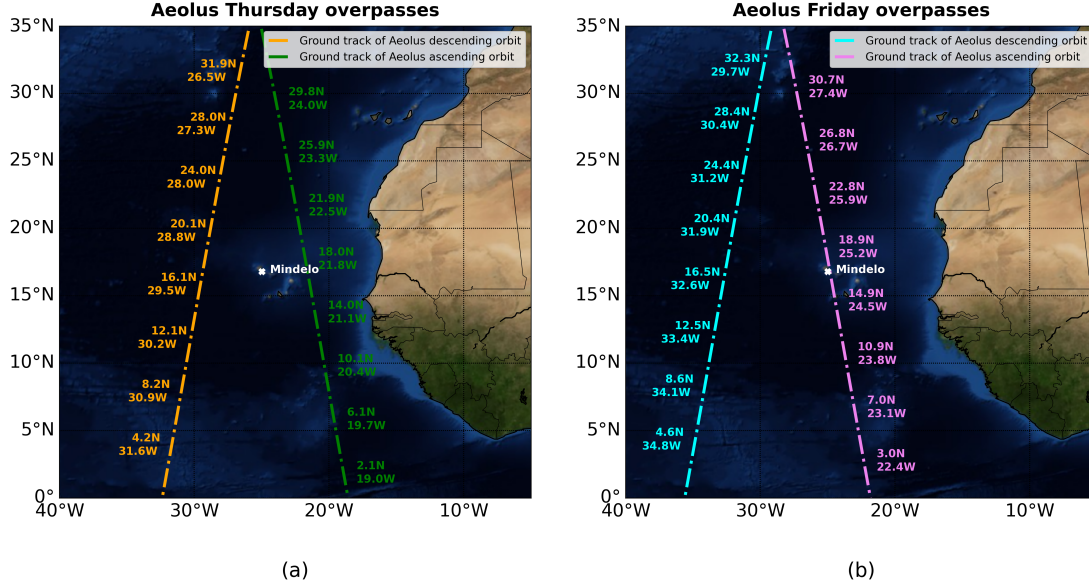

Figure 2. Aeolus closest overpasses to Cabo Verde for September 2022 (Blue Marble collection used for background map, Courtesy: <https://visibleearth.nasa.gov/>).

3.2 NASA Langley High-Altitude Lidar Observatory (HALO) and 532 nm aerosol products

The NASA HALO on-board the DC-8 aircraft was operated during CPEX-CV, which was a part of JATAC 2022. It is a differential absorption lidar (DIAL) and HSRL with multiple configurations including water vapor DIAL and HSRL, and methane DIAL and HSRL (Barton-Grimley et al., 2022; Bedka et al., 2021; Carroll et al., 2022; Nehrir et al., 2017, 2018).

155 For CPEX-CV, HALO operated in the water vapor DIAL and HSRL configuration to retrieve water vapor profiles as well as profiles of optical properties of atmospheric aerosols from multiple wavelength observations (532 nm, 1064 nm). HALO does not emit UV signal at 355 nm such as Aeolus ALADIN and a wavelength conversion is therefore required when carrying out comparisons. The spectral dependence of optical properties for desert dust is known to be less pronounced between 355 nm and 532 nm than between 355 nm and 1064 nm (Burton et al., 2015; Groß et al., 2013, 2015; Haarig et al., 2017b, 2018; Hofer

160 et al., 2017). Therefore, HALO products at 532 nm are preferred over the products at 1064 nm for the conversion to 355 nm. Moreover HALO transmits linear polarization whereas Aeolus transmits circular polarization. Therefore, the circular aerosol depolarization ratio is derived from the HALO ready-to-use linear aerosol depolarization ratio at 532 nm. HALO aerosol extinction and backscatter coefficients, respectively labelled $\alpha_{\text{aer},532}$ and $\beta_{\text{aer},532}$, are taken as input for the cross-comparison with MLEsub retrievals. The HALO attenuated backscatter coefficient at 532 nm labelled $\beta_{\text{aer},532}^{\text{att}}$ is selected for the cross-

165 comparison with SCA retrievals. HALO total scattering ratio at 532 nm labelled R_{532} , HALO linear aerosol depolarization

ratio at 532 nm labelled $\delta_{\text{lin},532}$, and HALO dominant aerosol type product based on Burton et al. (2012) typing algorithms are used as third variable distribution in the two-dimensional histograms with colormap.

The calculation of the HALO 532 nm ready-to-use products is described within the HALO documentation as below and in more detail in Hair et al. (2008).

170 Aerosol extinction coefficient at 532 nm:

$$\alpha_{\text{aer},532} = -\frac{1}{2} \frac{\partial}{\partial r} \ln \left\{ \frac{r^2 P_{\text{mol}}^{\parallel}}{F \psi \beta_{\text{mol},532}} \right\} - \alpha_{\text{mol},532} \quad (1)$$

With $\beta_{\text{mol},532}$ the molecular backscatter coefficient at 532 nm, $\alpha_{\text{mol},532}$ the molecular extinction coefficient at 532 nm, r the range from the DC-8 aircraft to the measurement bin, F is the transmission of the molecular scattering through the iodine filter, ψ is the transmitter-to-receiver overlap function (which is considered unity beyond 1.0 km range from the aircraft), and $P_{\text{mol}}^{\parallel}$ is filtered molecular scattering channel measured through the iodine vapor filter.

Aerosol backscatter coefficient at 532 nm:

$$\beta_{\text{aer},532} = \beta_{\text{aer},532}^{\parallel} + \beta_{\text{aer},532}^{\perp} \quad (2)$$

With $\beta_{\text{aer},532}^{\perp}$ the perpendicular (cross-polarized) aerosol backscatter coefficient at 532 nm and $\beta_{\text{aer},532}^{\parallel}$ the parallel (co-polarized) aerosol backscatter coefficient at 532 nm.

180 Linear aerosol depolarization ratio at 532 nm:

$$\delta_{\text{lin},532} = \frac{\beta_{\text{aer},532}^{\perp}}{\beta_{\text{aer},532}^{\parallel}} \quad (3)$$

Total scattering ratio at 532 nm:

$$R_{532} = \frac{\beta_{\text{aer},532}}{\beta_{\text{mol},532}} + 1 \quad (4)$$

With $\beta_{\text{aer},532}$ the aerosol backscatter coefficient at 532 nm.

185 4 Methodology

4.1 Conversion of the HALO 532 nm atmospheric products to parallel 355 nm

Aeolus ALADIN transmits circularly polarized light. The conversion of HALO signal to 355 nm then implies to derive the circular aerosol depolarization ratio at 532 nm using equation (A14) from Paschou et al. (2022):

$$\delta_{\text{circ},532} = \frac{2 * \delta_{\text{lin},532}}{1 - \delta_{\text{lin},532}} \quad (5)$$

190 Aeolus only measures the co-polarized component of the backscattered light, i.e., parallel to the transmitted polarization. Therefore to be fairly compared with Aeolus the HALO parallel-only aerosol backscatter 532 nm coefficient $\beta_{\text{aer},532}^{\parallel}$ is derived from Eqs. (2), (3) and (5):

$$\beta_{\text{aer},532}^{\parallel} = \frac{\beta_{\text{aer},532}}{\delta_{\text{circ},532} + 1} \quad (6)$$

The $\delta_{\text{lin},532}$ and derived $\delta_{\text{circ},532}$ include Not a Number (NaN) values, which represent noisy retrievals below the value of zero
 195 depolarization. It was decided to replace these NaN with value of zero. This allows to assess the Aeolus algorithm performance even for regions of the atmosphere without depolarizing particles.

It is necessary to convert the HALO 532 nm aerosol backscatter $\beta_{\text{aer},532}$ and extinction $\alpha_{\text{aer},532}$ to 355 nm using equations (1) and (3) of Ansmann et al. (2002) below with $\lambda_1 < \lambda_2$, $\gamma_{\beta,\lambda_1,\lambda_2}$ the backscatter-related Ångström exponent and $\gamma_{\alpha,\lambda_1,\lambda_2}$ the extinction-related Ångström exponent:

$$\gamma_{\beta,\lambda_1,\lambda_2} = -\frac{\ln[\beta_{\lambda_1}/\beta_{\lambda_2}]}{\ln(\lambda_1/\lambda_2)} \quad (7)$$

$$\gamma_{\alpha,\lambda_1,\lambda_2} = -\frac{\ln[\alpha_{\lambda_1}/\alpha_{\lambda_2}]}{\ln(\lambda_1/\lambda_2)} \quad (8)$$

Then the HALO 355 nm parallel aerosol backscatter $\beta_{\text{aer},355}^{\parallel}$ and extinction coefficient $\alpha_{\text{aer},355}$ can be derived from Eqs. (7) and (8):

$$\beta_{\text{aer},355}^{\parallel} = \exp \left[\ln(\beta_{\text{aer},532}^{\parallel}) - \gamma_{\beta,355,532} \ln \left(\frac{355}{532} \right) \right] \quad (9)$$

$$\alpha_{\text{aer},355} = \exp \left[\ln(\alpha_{\text{aer},532}) - \gamma_{\alpha,355,532} \ln \left(\frac{355}{532} \right) \right] \quad (10)$$

Backscatter-related Ångström exponent $\gamma_{\beta,355,532}$ and extinction-related Ångström exponent $\gamma_{\alpha,355,532}$ have been measured continuously by Polly^{XT} at Mindelo. The profiles of the optical properties measured by the Polly^{XT} are cloud-screened and quality assured. A Saharan Air Layer (SAL) was frequently observed between 1.5 and 4.0 km height.

During 09 September 2022, a median $\gamma_{\beta,355,532}$ of -0.39 (-0.51 and -0.31 are the 25th and 75th percentile, respectively) was
 210 derived in this height range (SAL) from 3 profiles during nighttime. On the same day and height range, a median $\gamma_{\alpha,355,532}$ of -0.09 (-0.5 and 0.43) was derived from 2 Raman lidar profiles during nighttime. The values in brackets again correspond to the 25th and 75th percentile. Similarly, median values of 0 (-0.01 and 0.02) for the $\gamma_{\beta,355,532}$ (3 nighttime profiles) and 0.06 (0.03 and 0.12) for the $\gamma_{\alpha,355,532}$ (3 nighttime profiles) have been estimated by Polly^{XT} for the height range of 0.8 – 1.0 km corresponding to the Planetary Boundary Layer (PBL).

215 During 15 September 2022, a median $\gamma_{\beta,355,532}$ of -0.44 was derived in the SAL height range from 1 profile during nighttime. On the same day and height range, a median $\gamma_{\alpha,355,532}$ of 0.06 (-0.48 and 0.58) was derived from 3 Raman lidar profiles during nighttime. Similarly, median values of 0.23 for the $\gamma_{\beta,355,532}$ (1 nighttime profile) and 0.14 (0.01 and 0.22) for the $\gamma_{\alpha,355,532}$ (5 nighttime profiles) have been estimated by Polly^{XT} for the PBL height range.

220 During 16 September 2022, a median $\gamma_{\beta,355,532}$ of -0.43 (-0.68 and -0.25) was derived in the SAL height range from 9 profiles during nighttime. On the same day and height range, a median $\gamma_{\alpha,355,532}$ of 0.11 (-0.21 and 0.48) was derived from 11 Raman lidar profiles during nighttime. Similarly, median values of 0.31 (0.17 and 0.41) for the $\gamma_{\beta,355,532}$ (9 nighttime profile) and 0.24 (0.13 and 0.38) for the $\gamma_{\alpha,355,532}$ (16 profiles) have been estimated by Polly^{XT} for the PBL height range.

The close-to-zero extinction-related Ångström exponent and negative backscatter-related Ångström exponent are known to be representative for mineral dust (Floutsi et al., 2023; Gebauer et al., 2024; Haarig et al., 2022). For the present study the SAL values are applied from 1.5 km altitude to top altitude of 10 km as the HALO dominant aerosol type product reveals similar aerosol load below and above 4 km altitude (see Appendix A1, Appendix A2, and Appendix A3) and because the impact on tropospheric background in aerosol-free regions is assumed to be minor. The PBL value are applied for the section going from the ground to 1.5 km altitude.

The HALO 355 nm attenuated backscatter coefficient for particles $\beta_{\text{aer},355}^{\text{att||}}$ can be calculated with Eqs. (9) and (10) as follows:

$$\beta_{\text{aer},355}^{\text{att||}} = \beta_{\text{aer},355}^{\text{||}}(R) \exp \left[-2 \int_{z_{\text{aircraft}}}^z (\alpha_{\text{mol},355}(y) + \alpha_{\text{aer},355}(y)) dy \right] \quad (11)$$

With R the DC-8 aircraft range-to-target, dy the range bin thickness, z_{aircraft} the Global Positioning System (GPS) altitude of the DC-8 aircraft, z the altitude of mean sea level, $\alpha_{\text{mol},355}$ the molecular extinction coefficient for dry air. The $\alpha_{\text{mol},355}$ below the DC-8 is derived from pressure p (hpa) and temperature T (K) measured by HALO. The equation (4.6) of Aeolus Level 2A Algorithm Theoretical Basis Document (ATBD) (Flamant et al., 2022) shown below has been used for the calculation of $\alpha_{\text{mol},355}$ using a coefficient of 1.16 which was determined experimentally (Collis and Russell, 1976).

$$\alpha_{\text{mol},355}(y) = 1.16 \left(\frac{550}{355} \right)^{4.09} \frac{p(y)}{1013} \frac{288}{T(y)} 10^{-5} \quad (12)$$

The molecular extinction above the DC-8 up to 80 km altitude is calculated using the same equation with pressure and temperature information from Numerical Weather Prediction (NWP) model from the European Centre for Medium-Range Weather Forecasts (ECMWF). It has to be noted that the flight altitude of the DC-8 is constant enough for the three collocated sections selected for the study to neglect variations. A mean value of $5.0 \times 10^{-4} \text{ m}^{-1}$ has been calculated for the molecular extinction above the DC-8 and used as a constant for all scenes. This constant is added to the $\alpha_{\text{mol},355}$ derived in Eq. (12) when calculating the $\beta_{\text{aer},355}^{\text{att||}}$ in Eq. (11).

Aeolus MLEsub extinction and backscatter coefficients for particles, and SCA particulate attenuated backscatter coefficient, can then be compared with the 355 nm converted HALO atmospheric products. Only the valid bins with positive values are considered for the statistics (i.e., the invalid measurements coded as NaN in one product being ignored on the second dataset and vice-versa). The flagging of the negatives is applied for all Aeolus and HALO products used in the cross-comparisons. The HALO and Aeolus cloud masks are not applied to keep as many valid bins as possible. This helps assessing how well Aeolus observes Saharan dust and mixture of aerosol and cloud, the HALO dominant aerosol type product being used as ad-hoc classification.

4.2 HALO re-gridding onto Aeolus sampling

One of the major advantages of Aeolus is the adjustable vertical sampling with Range Bin Settings (RBS). Specific settings have then been set for the region of interest over the Atlantic covering latitudes 12° N to 22° N and longitudes 19° W to 31° W. The top height bin stops at ≈ 18 km altitude and the following vertical sampling have been applied: 500 m from 0 to ≈ 2 km

altitude, 750 m from ≈ 2 km to ≈ 8 km altitude, 1000 m from ≈ 8 km to ≈ 18 km. The horizontal sampling is aligned with \approx
 255 90 km for the coarser observation level BRC and with ≈ 18 km for finer sub-BRC level measurement used for the comparison
 with HALO data.

The HALO 532 nm channels are sampled at 0.5 s temporal and 1.25 m vertical resolutions. The data are digitally filtered
 to 30 m vertical resolution to further reduce noise and match the vertical resolution of the 1064 nm data products. Aerosol
 backscatter and depolarization products are further averaged 10 s horizontally and aerosol extinction products are averaged
 260 60 s horizontally and 300 m vertically. A ready-to-use quality flagging based on molecular backscatter signal and referred
 as mask_low was applied. A cloud identification tag and height named cloud_top_height was used and plotted over HALO
 atmospheric products (Figs. 5a-c, 7a-c, 9a-c).

The resolutions of Aeolus ALADIN and DC-8 HALO instruments are then not aligned. Figure 3b illustrates the Aeolus
 finer horizontal resolution, i.e., so-called measurement level (solid black lines), superimposed over HALO 532 nm aerosol
 265 backscatter coefficient. Then 225 consecutive HALO profiles covering a collocated section of ≈ 538 km on 16 September
 2022 correspond to 6 Aeolus BRC (Fig. 3a) and 30 Aeolus measurement profiles (Fig. 3b). The focus being given to Aeolus
 performance, the HALO atmospheric products are re-gridded onto the coarser Aeolus measurement scale. The HALO 355 nm
 converted aerosol extinction $\alpha_{\text{aer},355}$, the HALO 355 nm converted parallel aerosol backscatter $\beta_{\text{aer},355}^{\parallel}$, and the HALO 355 nm
 converted attenuated backscatter for particles $\beta_{\text{aer},355}^{\text{att}\parallel}$ are then re-gridded onto Aeolus grid by deriving the arithmetic mean per
 270 range bin for each profile. The equation below corresponds to the HALO 355 nm aerosol backscatter averaged over the Aeolus
 grid illustrated in Fig. 3b:

$$\beta_{\text{iAeolus}}(\text{Mm}^{-1}\text{sr}^{-1}) = \frac{\sum \beta_{\text{iHALO}}(\text{Mm}^{-1}\text{sr}^{-1})}{N} \quad (13)$$

With N the amount of HALO bins iHALO included per Aeolus range bin iAeolus.

Invalid HALO measurements that correspond to localized conditions, e.g., below dense clouds or within the PBL, and
 275 reported as NaN values in the ready-to-use products are not taken into account in the re-gridding. The re-gridding is then
 performed even where the Aeolus coarser grid encompasses valid and invalid HALO retrievals (e.g., white section of HALO
 $\beta_{\text{aer},532}$ close to profile 114 [15.7° N - 24.7° W] in Fig. 3b), hence a gap filling. The cross-comparison between Aeolus and
 HALO could then be considered less representative for such conditions if compared to fully valid bin. Moreover the atmo-
 spheric conditions above the DC-8 aircraft have been analysed using Aeolus aerosol products and only the tropospheric sec-
 280 tions with clear sky conditions above the DC-8 are considered for the study. This enables to reject collocated profiles where
 the Aeolus signal can be expected to be attenuated.

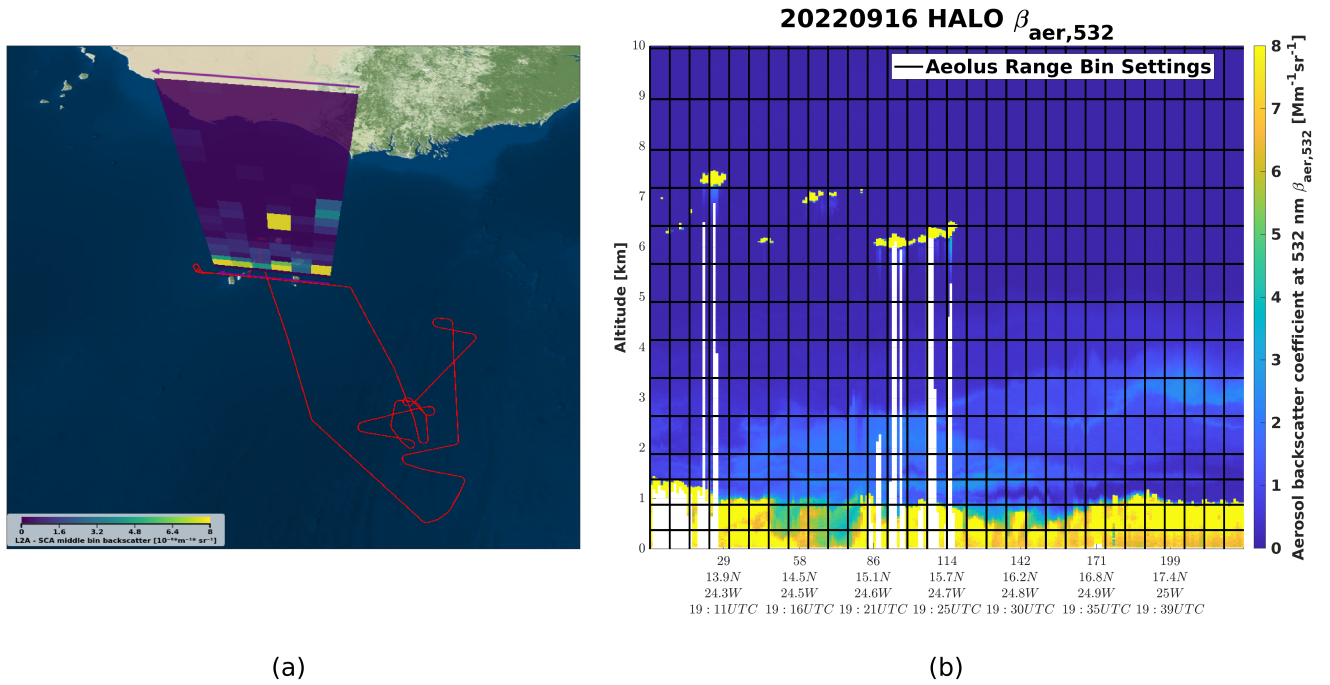

Figure 3. Aeolus direct ascending overpass above Cabo Verde through ESA VirES (Downloaded on August 07 2023, Courtesy: <https://aeolus.services/>) on 16 September 2022 (a) showing the backscatter coefficient for particles derived with SCA algorithm (averaged over consecutive vertical bin and referred as middle bin). The horizontal resolution is aligned with coarser BRC level ≈ 90 km. The 6 consecutive BRC of Aeolus orbit file no. 23562 are displayed (a). The top altitude is restricted to 10 km and the range bins are not displayed in scale vertically. The 6 Aeolus BRC correspond to 30 measurements given at sub-BRC level ≈ 18 km (b). The Aeolus sub-BRC grid is illustrated in (b) with solid black lines. The NASA DC-8 flight track of the same day is superimposed in red color code (a). The HALO aerosol backscatter coefficient at 532 nm $\beta_{\text{aer},532}$ measured for 225 consecutive profiles is shown in (b).

5 Results

5.1 Intercomparison of aerosol profiles collocated with ground-based instrument

The HALO atmospheric product converted to 355 nm have been compared to Aeolus for three case studies on 09 September 2022, 15 September 2022, and 16 September 2022. These three case studies correspond to collocated sections with continuous measurement of respectively ≈ 626 km, ≈ 537 km and ≈ 538 km long. Figures 4a, A4a and A5a illustrate how the Aeolus MLEsub β_{part} up to 18 km altitude helps assessing the particle-free conditions above the DC-8 aircraft flying at ≈ 10 to 11 km altitude. No backscatter signal corresponding to aerosol layers or clouds can be observed above 10 km altitude, confirming the clear sky conditions (e.g., Fig. 4a with dark blue color code pointing to close-to-zero MLEsub β_{part}) above the DC-8. The 2D profiles above Cabo Verde from Aeolus MLEsub and HALO are plotted against ground-based lidar Polly^{XT}. The Polly^{XT} emits linear polarization (Engelmann et al., 2016) with off-nadir $\approx 5^\circ$ but Aeolus transmits circularly polarized light. The Polly^{XT}

circular aerosol depolarization ratio at 355 nm is then derived to recompute the parallel backscatter coefficient at 355 nm with equations similar to Eqs. (5) and (6). Plotting Polly^{XT} retrievals in addition to Aeolus and HALO for direct profiles above Mindelo, Cabo Verde enables to validate the wavelength and total to parallel conversions before comparing Aeolus and HALO with full collocated section. Figure 4b shows the Polly^{XT} total 355 nm backscatter (i.e., red) and parallel 355 nm backscatter (i.e., blue), and illustrates how the HALO total 532 nm backscatter coefficient $\beta_{\text{aer},532}$ (i.e., black) was converted to parallel 355 nm $\beta_{\text{aer},355}^{\parallel}$ (i.e., dark yellow). Both profiles of the parallel 355 nm backscatter retrieved with Raman Polly^{XT} and HALO agree very well with Aeolus MLEsub (i.e., violet) for the SAL from ≈ 2.6 km to 4 km altitude. MLEsub β_{part} of $1.36 \text{ Mm}^{-1}\text{sr}^{-1} \pm 0.56 \text{ Mm}^{-1}\text{sr}^{-1}$ and HALO $\beta_{\text{aer},355}^{\parallel}$ of $1.14 \text{ Mm}^{-1}\text{sr}^{-1} \pm 0.02 \text{ Mm}^{-1}\text{sr}^{-1}$ are measured for the in-core SAL at 3 km altitude. The red solid line for Polly^{XT} 355 nm total backscatter represents what Aeolus should see if it would have included a polarization channel, then increasing the backscatter signal by a factor $\approx 34 \%$ for the in-core dust layer at 3 km altitude. When looking at the extinction coefficient for particles, Aeolus MLEsub also agrees with the other instruments even if the Aeolus signal appears to be too much attenuated and therefore flagged below 3 km altitude. One could notice the high errors for MLEsub α_{part} . Similar observations can be made with cases 09 September 2022 (see Appendix A4) and 15 September 2022 (see Appendix A5). The Aeolus MLEsub is able to retrieve coherent optical properties in low altitude ≈ 1 km below dust with high backscatter up to $9.45 \text{ Mm}^{-1}\text{sr}^{-1} \pm 2.12 \text{ Mm}^{-1}\text{sr}^{-1}$ (see Appendix A4b), even if this looks overestimated when compared to the other instrument retrievals below $7.0 \text{ Mm}^{-1}\text{sr}^{-1}$. The Aeolus MLEsub gives coherent backscatter values for a dense SAL around 4 km altitude on 15 September 2022 (Fig. A5b) even considering a larger geolocation offset from the Polly^{XT} (i.e., ≈ 350 km, instead of ≈ 13 km for 09 September 2022 and ≈ 20 km for 16 September 2022). Figures 4b-c, A4b-c and A5b-c illustrate how the HALO 355 nm converted signals, even coming with low errors, may vary per Aeolus vertical range bin. This results in variabilities when re-gridding onto Aeolus sampling, and it is a limitation of the cross-section comparison. Another limitation is illustrated with the offset between HALO and Polly^{XT} 355 nm converted signals as it reveals uncertainties from the wavelength conversion.

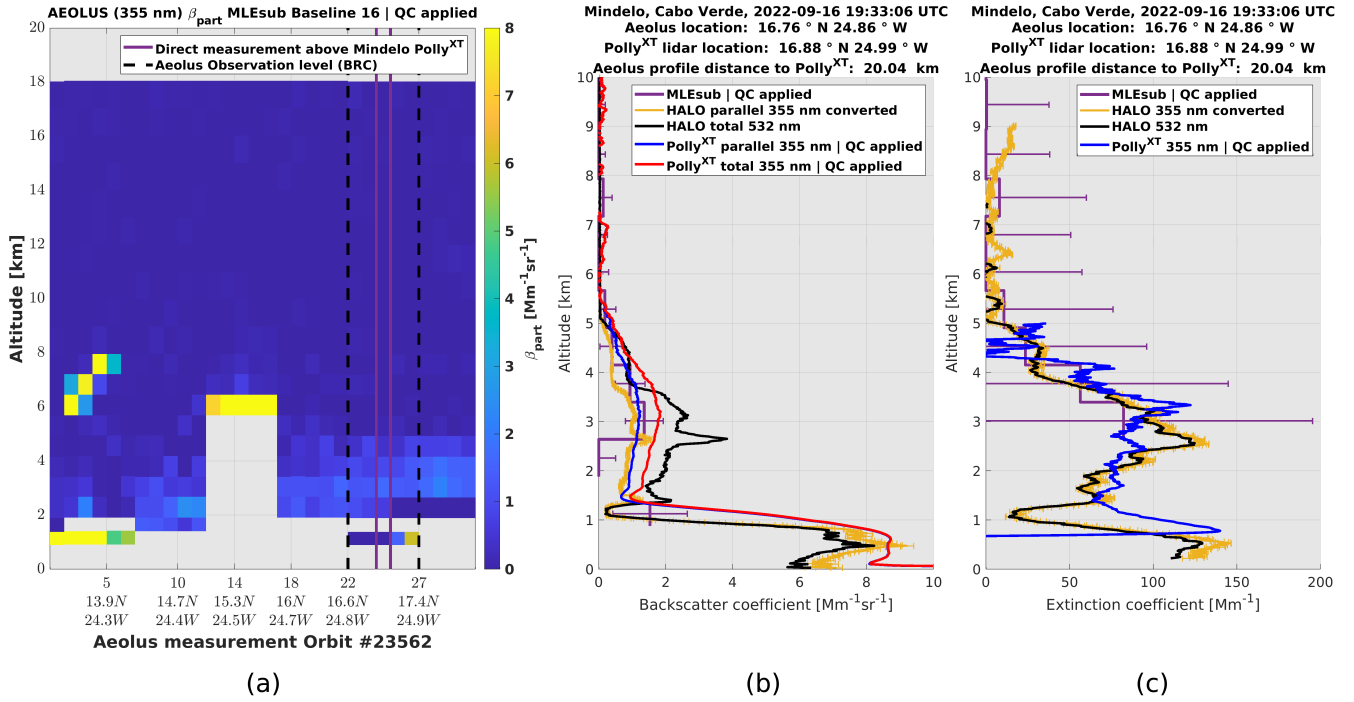

Figure 4. Aeolus MLEsub β_{part} on 16 September 2022 (a) and cross of 2D profiles above Mindelo, Cabo Verde with HALO and Polly^{XT} for MLEsub β_{part} (b) and MLEsub α_{part} (c).

5.2 Cross comparison of tropospheric sections observed by Aeolus ALADIN and DC-8 HALO

315 A linear regression has been applied with the log transformed signals. Working with logarithmic scale helps decreasing the sensibility to outliers which may be expected in low SNR regions. Moreover it offers a better visualization of regimes within two-dimensional histograms. The three indicators R^2 , slope of the regression line and the Root Mean Square Error (RMSE) have been calculated with the log transformed signals for each collocated section. The Table 1 below summarizes the scores. The R^2 for MLEsub backscatter β_{part}^{\parallel} and MLEsub extinction α_{part} are robust, i.e., respectively up to 0.69 and 0.58, showing
320 good agreement with HALO retrievals. Interestingly the higher R^2 scores correspond to 09 September 2022 for both MLEsub backscatter and SCA particulate attenuated backscatter $\beta_{part}^{att\parallel}$, the 15 September 2022 case showing the higher R^2 for MLEsub extinction. For each scene the section details are introduced before analysing the cross between HALO converted and re-gridded signals and the Aeolus products.

		Sep. 09	Sep. 15	Sep. 16
$\beta_{\text{part}}^{\parallel}$	R^2	0.69	0.56	0.60
	Slope	0.89	0.71	0.82
	RMSE	0.59	0.59	0.64
α_{part}	R^2	0.41	0.58	0.25
	Slope	1.08	1.09	0.71
	RMSE	0.68	0.66	0.73
$\beta_{\text{part}}^{\text{att}\parallel}$	R^2	0.48	0.28	0.14
	Slope	0.39	0.29	0.23
	RMSE	0.77	0.79	0.97

Table 1. Summary table showing the statistics of the linear regression Aeolus MLEsub $\beta_{\text{part}}^{\parallel}$, MLEsub α_{part} , and SCA $\beta_{\text{part}}^{\text{att}\parallel}$ versus HALO 355 nm converted and re-gridded signals. The scores are derived from the log transformed signals.

5.2.1 Case study 9 September 2022

Cross section details. Figures 5a-c show HALO 355 nm converted (top) and re-gridded (middle), and Aeolus 355 nm (bottom) aerosol retrievals for a collocated section of ≈ 626 km horizontal from $\approx [13.3^\circ \text{ N} - 24.3^\circ \text{ W}]$ to $\approx [18.8^\circ \text{ N} - 25.3^\circ \text{ W}]$. A total of 271 HALO profiles can be re-gridded onto 35 collocated Aeolus measurements. Geolocation offset for the first collocated measurement is equal to ≈ 5.2 km and initial time offset is equal to ≈ 9 minutes.

HALO against Aeolus MLEsub. HALO cloud_top_height superimposed over parallel 355 nm converted particulate backscatter revealed a marine boundary layer (MBL) up to ≈ 1 km altitude with values above $8 \text{ Mm}^{-1}\text{sr}^{-1}$ (Fig. 5a top, light yellow color code). Low altitude clouds are dominant close to HALO profile $\approx 103 [15.3^\circ \text{ N} - 24.6^\circ \text{ W}]$ and last tier of the section above HALO profile $\approx 205 [17.4^\circ \text{ N} - 25.0^\circ \text{ W}]$. Stratified marine and dusty mix aerosol layers can be seen up to ≈ 4 km altitude with backscatter from ≈ 3.0 to $5.0 \text{ Mm}^{-1}\text{sr}^{-1}$ (Fig. 5a, light blue to green color codes) as confirmed with HALO dominant aerosol type (see Appendix A1). Aeolus captures well the scene even applying the restrictive quality flags, which are removing the lowest range bin below 1 km altitude except for cloudy region below dust in the last tier of the orbit section. The signature of dust particles mixture can indeed be observed on top of the MBL (Fig. 5b bottom, light blue to green pattern with extinction close to $\approx 150 \text{ Mm}^{-1}$). The signature of the dust layer at ≈ 3 km altitude close to second-last Aeolus measurement 34 is even more clear. The Aeolus extinction is also flagged below the dusty mix around ≈ 1.8 km altitude. This is a confirmation of a signal attenuation with low SNR.

The Aeolus backscatter (Fig. 5a bottom) appears lower for cloud top echos when compared to HALO 355 nm converted product before re-gridding (Fig. 5a top). For example, the HALO backscatter reach values above $8.0 \text{ Mm}^{-1}\text{sr}^{-1}$ (Fig. 5a top, light yellow) for localized cloud in ≈ 2 km altitude for HALO profile 30 $[13.8^\circ \text{ N} - 24.3^\circ \text{ W}]$, and Aeolus reported backscatter is $\approx 4.6 \text{ Mm}^{-1}\text{sr}^{-1}$ (Fig. 5a bottom, light green) for Aeolus measurement 4 at similar altitude of ≈ 2 km. This confirms that Aeolus signal averaging with scattered or broken clouds may result in cloud echos dilution when the range bin encompasses

345 contribution of lower backscatter signal from the surroundings. The averaging dilution is expected to be more pronounced with lower vertical resolution, i.e., with thicker range bin, and with coarser horizontal resolution of ≈ 90 km for BRC level products.

Plotting the 355 nm converted and re-gridded HALO against Aeolus MLEsub for the whole scene reveals R^2 scores of 0.69 for backscatter (Fig. 6a) and 0.41 for extinction (Fig. 6b) with respective slope for the regression line of 0.89 and 1.08. The agreement between Aeolus and HALO then appears consistent. Two dominant regimes can be identified using HALO 532 nm linear aerosol depolarization ratio $\delta_{\text{lin},532}$. The first one is indicated in cyan color code and corresponds to low backscatter signal (Fig. 6a) with HALO total scattering ratio at 532 nm R_{532} below a threshold of 1.2, which is required for HALO aerosol classification, hence the Not identified type (Fig. 6d, gray). The second regime comes with dominant red-orange color code with $\delta_{\text{lin},532}$ above ≈ 0.25 (Fig. 6a-b), then mainly attributed to dusty conditions (Freudenthaler et al., 2009). It is confirmed with a dusty mix class from HALO dominant aerosol type classification (Fig. 6d, dark violet). The HALO 532 nm circular aerosol depolarization ratio $\delta_{\text{circ},532}$ shows values above ≈ 0.35 for this regime. The best agreement coincides with the second regime connected to highly depolarizing particles. The use of HALO total scattering ratio at 532 nm R_{532} confirms that the first regime corresponds to low scattering (see Appendix A6, cyan color code). This provides further evidence that the first regime is linked to low SNR regions of the atmosphere in clear sky conditions.

HALO against Aeolus SCA. Evidence of the MBL is visible with SCA particulate attenuated backscatter $\beta_{\text{part}}^{\text{att}}$ (Fig. 5c, bottom) and the values look coherent even for the low range bins (i.e., up to $\approx 3.0 \times 10^{-3} \text{ km}^{-1} \text{ sr}^{-1}$). The top of the MBL is captured for the overall section. The SCA $\beta_{\text{part}}^{\text{att}}$ shows values below $\approx 2.0 \times 10^{-3} \text{ km}^{-1} \text{ sr}^{-1}$ for the dust above ≈ 2 km (Fig. 5c, light blue color code) which is hardly distinguishable from background noise in last tier of the orbit. When compared to the HALO 355 nm converted signal, these SCA $\beta_{\text{part}}^{\text{att}}$ values look underestimated. The scatter diagram confirms an underestimation of the SCA particulate attenuated backscatter for the second regime. The SCA seems to overestimate the backscatter for the first regime in low scattering regions of the atmosphere (Appendix A7, cyan color code). When removing this regime from the analysis using HALO R_{532} and applying a threshold of 1.2 the R^2 increases from 0.48 to 0.52 and the RMSE decreases from 0.77 to 0.70. A positive impact is also observed for MLEsub backscatter (i.e., R^2 increasing from 0.69 to 0.71 and RMSE decreasing from 0.59 to 0.43) and extinction (i.e., R^2 increasing from 0.41 to 0.47 and RMSE decreasing from 0.68 to 0.38). Interestingly, a third regime in high backscatter regions can be identified with $\delta_{\text{lin},532}$ from ≈ 0.05 to ≈ 0.10 (Fig. 6c, dark blue), the $\delta_{\text{circ},532}$ reaching values of order ≈ 0.10 to ≈ 0.20 . The HALO dominant aerosol type points to mixture of marine aerosols and dusty mix (Fig. 6f, blue and dark violet color codes). The SCA appears to underestimate the signal for this regime which includes marine aerosols.

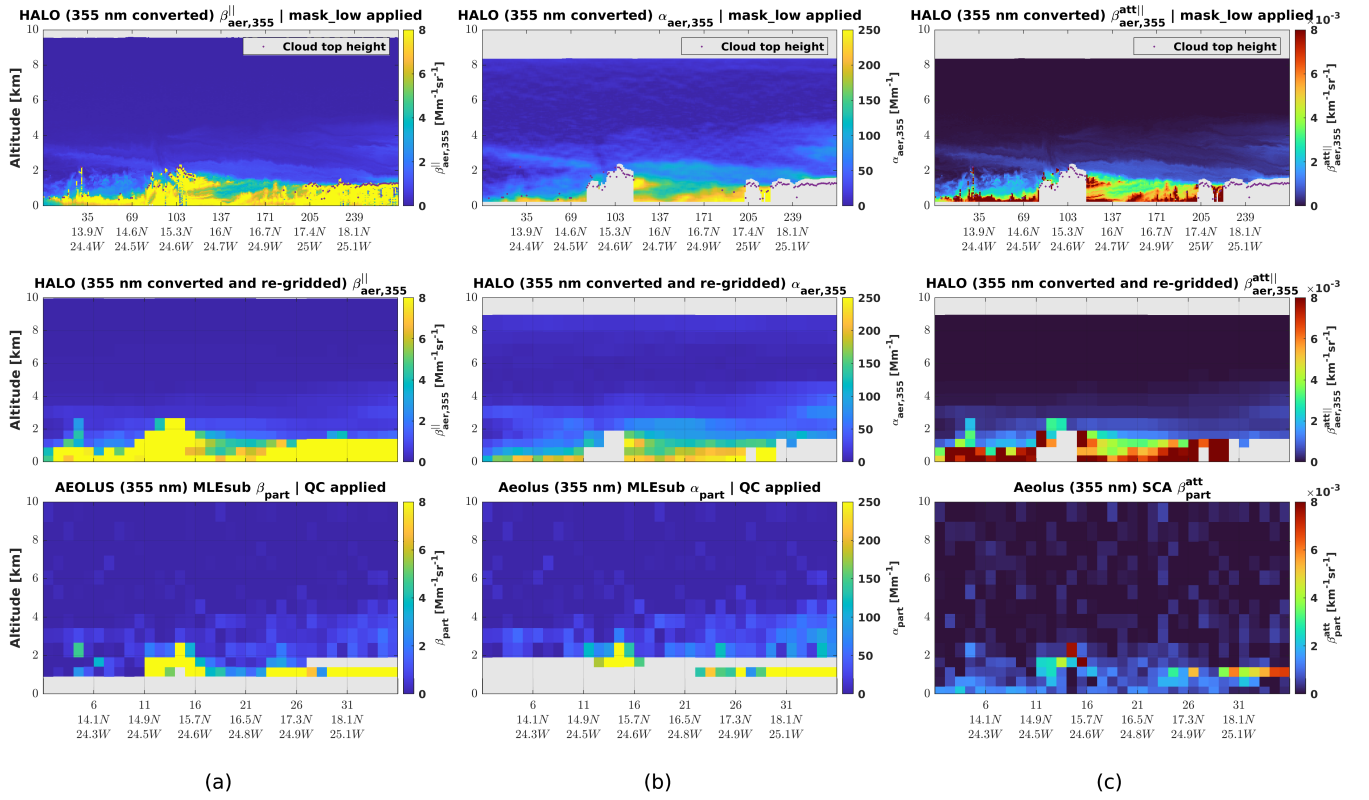

Figure 5. Aeolus MLEsub β_{part} (a), MLEsub α_{part} (b), and SCA β_{part}^{att} (c) cross section collocated with HALO 355 nm converted products on 09 September 2022.

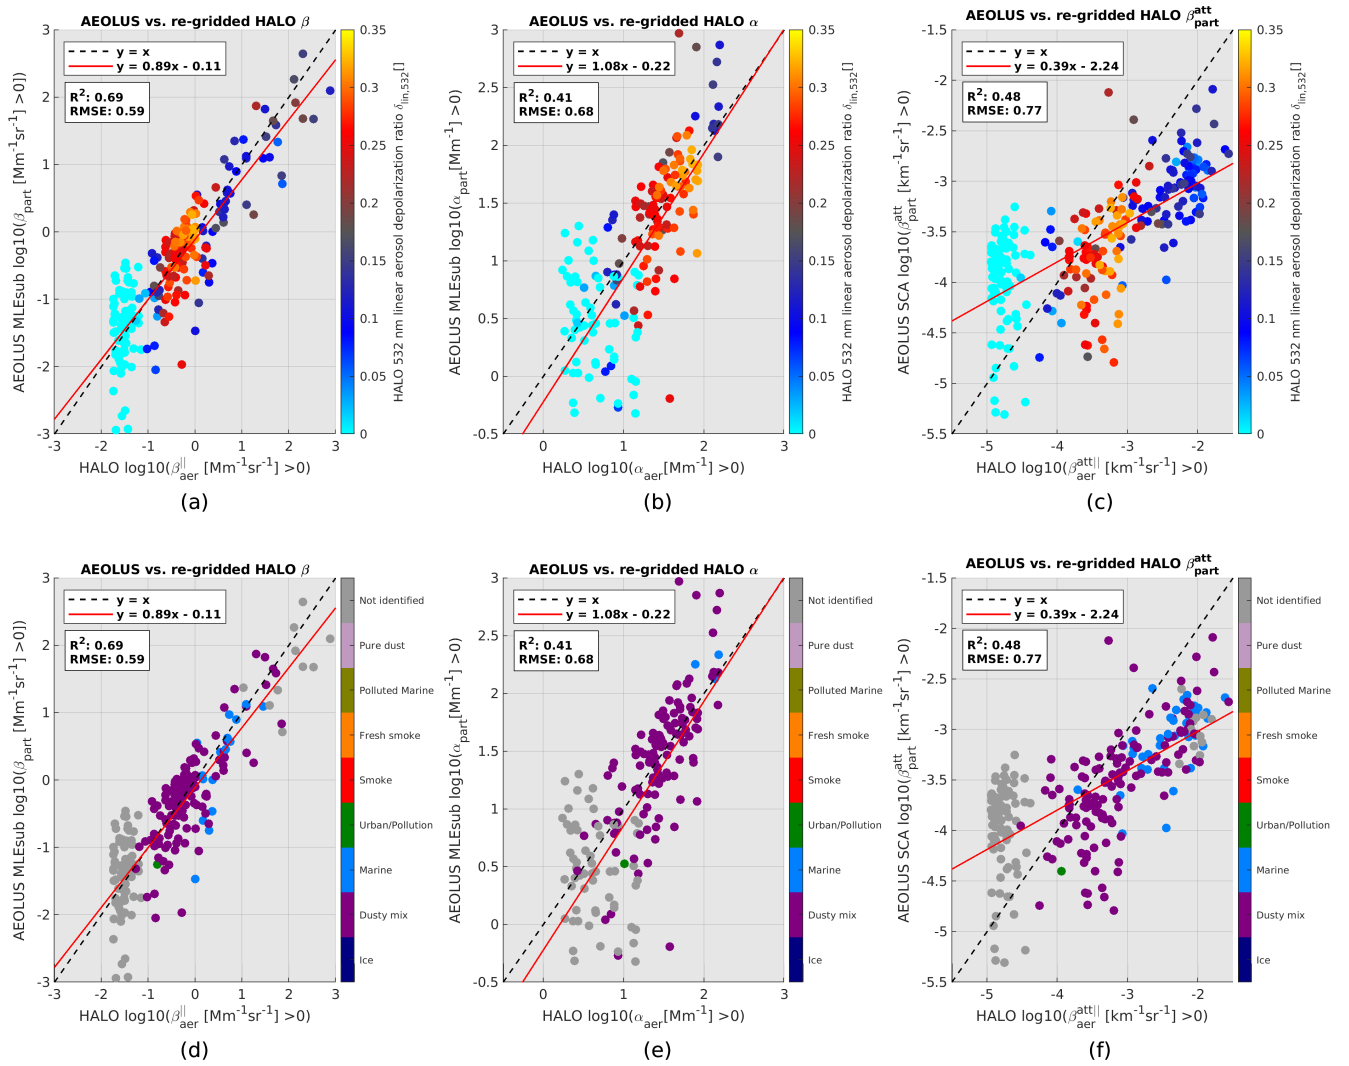

Figure 6. Two-dimensional histograms of Aeolus versus HALO 355 nm converted and re-gridded products with HALO $\delta_{\text{circ},532}$ as colors (a-c) and with HALO dominant aerosol type as colors (d-f) on 09 September 2022. A logarithmic transformation has been applied to the signals.

5.2.2 Case study 15 September 2022

Cross section details. Figures 7a-c show HALO 355 nm converted (top) and re-gridded (middle), and Aeolus 355 nm (bottom) aerosol retrievals for a collocated section of ≈ 537 km horizontal from $\approx [15.9^\circ \text{ N} - 21.5^\circ \text{ W}]$ to $\approx [20.7^\circ \text{ N} - 22.4^\circ \text{ W}]$. A total of 218 HALO profiles can be re-gridded onto 30 collocated Aeolus measurements. Geolocation offset for the first collocated measurement is equal to ≈ 3.8 km and initial time offset is equal to ≈ 13 minutes.

HALO against Aeolus MLEsub. HALO cloud_top_height superimposed over parallel 355 nm converted particulate backscatter shows optically dense MBL up to 0.5 km altitude (Fig. 7a, top). An homogeneous feature, spatially distributed over the scene, with backscatter up to $\approx 5.0 \text{ Mm}^{-1}\text{sr}^{-1}$ can be observed around 4 km altitude (light green to yellow color codes), which is typical for SAL height (Ansmann et al., 2009). HALO dominant aerosol type confirms the presence of dusty mix (see Appendix A2). The SAL is clearly captured by the MLEsub algorithm, the southern edge of the aerosol layer being particularly visible up to Aeolus measurement 18 [$18.7^\circ \text{ N} - 21.9^\circ \text{ W}$] with both MLEsub backscatter and extinction coefficients (Fig. 7a-b). The MLEsub products are flagged below this dense and homogeneous aerosol layer. The backscatter scatter diagram show robust agreement between Aeolus and HALO for the dusty mix regime (dark violet color code in Fig. 8d) with R^2 score of 0.56. This regime corresponds to a HALO $\delta_{\text{lin},532}$ above ≈ 0.25 (Fig. 8a, red-orange to yellow color codes) and HALO $\delta_{\text{circ},532}$ above ≈ 0.35 . The main deviations correspond to the first regime where aerosol loading is weak and falls below the classification threshold of 1.2 in HALO total scattering ratio at 532 nm R_{532} .

HALO against Aeolus SCA. The Aeolus SCA algorithm is able to capture well the dusty mix layer at ≈ 4 km (Fig. 7c bottom, light blue color code) and the MBL below ≈ 0.8 km. Values of particulate attenuated backscatter up to $\approx 8.0 \times 10^{-4} \text{ km}^{-1}\text{sr}^{-1}$ are measured for the southern edge of the aerosol layer close to Aeolus measurement 5 [$16.6^\circ \text{ N} - 21.6^\circ \text{ W}$]. The aerosol layer signature is less clear in the last tier of the scene, i.e. after Aeolus measurement 18 [$18.7^\circ \text{ N} - 21.9^\circ \text{ W}$] with SCA $\beta_{\text{part}}^{\text{att}}$ below $\approx 2.0 \times 10^{-4} \text{ km}^{-1}\text{sr}^{-1}$. This may be used as a first estimation for lower limit of SCA $\beta_{\text{part}}^{\text{att}}$ detection for dust particles. The scatter diagram shows R^2 score of 0.28 and the higher deviations are once more observed for low scattering (see Appendix A7). The better agreement is observed for the dusty mix regime (red-orange to yellow color codes in Fig. 8c). Removing the contributions from low scattering below HALO R_{532} of 1.2 has a significant impact on the slope (i.e., increased from 0.29 to 0.40).

Figure 7. Aeolus MLEsub β_{part} (a), MLEsub α_{part} (b), and SCA β_{part}^{att} (c) cross section collocated with HALO 355 nm converted products on 15 September 2022.

Figure 8. Two-dimensional histograms of Aeolus versus HALO 355 nm converted and re-gridded products with HALO $\delta_{circ,532}$ as colors (a-c) and with HALO dominant aerosol type as colors (d-f) on 15 September 2022. A logarithmic transformation has been applied to the signals.

5.2.3 Case study 16 September 2022

Cross section details. Figures 9a-c show HALO 355 nm converted (top) and re-gridded (middle), and Aeolus 355 nm (bottom) aerosol retrievals for a collocated section of ≈ 538 km horizontal from $\approx [13.2^\circ \text{ N} - 24.3^\circ \text{ W}]$ to $\approx [17.9^\circ \text{ N} - 25.1^\circ \text{ W}]$. A total of 225 HALO profiles can be re-gridded onto 30 collocated Aeolus measurements. Geolocation offset for the first collocated measurement is equal to ≈ 2 km and initial time offset is equal to ≈ 25 minutes.

HALO against Aeolus MLEsub. HALO cloud_top_height superimposed over parallel 355 nm converted particulate backscatter reveals some broken clouds at ≈ 6 km altitude in first tier of the tropospheric section. Two main stratified features with strong signatures are particularly noticeable. They are distributed between HALO profiles 29 [$13.9^\circ \text{ N} - 24.3^\circ \text{ W}$] to 142 [$16.2^\circ \text{ N} - 24.8^\circ \text{ W}$] at ≈ 2 km altitude and within last tier of the section by HALO profile ≈ 171 [$16.8^\circ \text{ N} - 24.9^\circ \text{ W}$] at ≈ 3 km altitude. HALO dominant aerosol type mainly classifies the two layers as pure dust (see Appendix A3). Aeolus captures well the two dust layers. They are particularly visible with Aeolus MLEsub extinction coefficient (Fig. 9b bottom, light blue to green color codes). A decrease of HALO 355 nm converted extinction can be observed in top altitude close to HALO profile 86 [$15.1^\circ \text{ N} - 24.6^\circ \text{ W}$].

The backscatter scatter diagram reveal good agreement between HALO and Aeolus with R^2 of 0.60. The best agreement correspond to the non-spherical particles regime classified as dusty mix by HALO dominant aerosol type product (i.e., dark violet color code in Fig. 10d). HALO and Aeolus are in very good agreement for the core dust layer (i.e., red-orange point clouds close to the $y = x$ line for Fig. 10a-b) classified as pure dust with HALO classification (Fig. 10d-e, rose color code). The HALO $\sigma_{\text{lin},532}$ reaches ≈ 0.30 for such layer that is indeed pointing to dust conditions (Freudenthaler et al., 2009; Haarig et al., 2017a, 2022). The HALO $\sigma_{\text{circ},532}$ shows values up to ≈ 0.40 for this pure dust regime. The ability of Aeolus to retrieve physical retrievals even for highly depolarizing particles such as SAL is then demonstrated. The larger outliers cannot be attributed to an aerosol type, and are distributed in aerosol-free regions with low and high backscatter (Fig. 10d, gray). This may point to low signal, and bins contaminated by clouds. The scene indeed includes dense clouds close to ≈ 6 km altitude (Fig. 9a). One could flag the cloudy regions applying a scattering ratio threshold of 5 (Chepfer et al., 2013; Feofilov et al., 2022). If combined with the low scattering removal (i.e., $1.2 < R_{532} \leq 5$), this has a positive impact (e.g., decrease of RMSE from 0.64 to 0.38 for the MLEsub backscatter and from 0.73 to 0.41 for the MLEsub extinction).

HALO against Aeolus SCA. The SCA underestimates the signal from the marine aerosol regime (Fig. 10f, blue). Both HALO and SCA reveal broken clouds around ≈ 6 km to ≈ 8 km for the first half of the orbit and the signature of the pure dust layer close to second-last Aeolus measurement 34 is observable within the SCA particulate attenuated backscatter (Fig. 9c, bottom) light blue color code). The scatter diagram shows R^2 score of 0.14 and the best agreement is observed for the pure dust and dusty mix regimes (dark violet and rose color codes in Fig. 10f) despite some outliers. The lowest correlation once more corresponds to low signal regions of the atmosphere (Fig. 10f, gray) with low scattering (Fig. A8c, cyan) for which the SCA appears to overestimate the particulate attenuated backscatter.

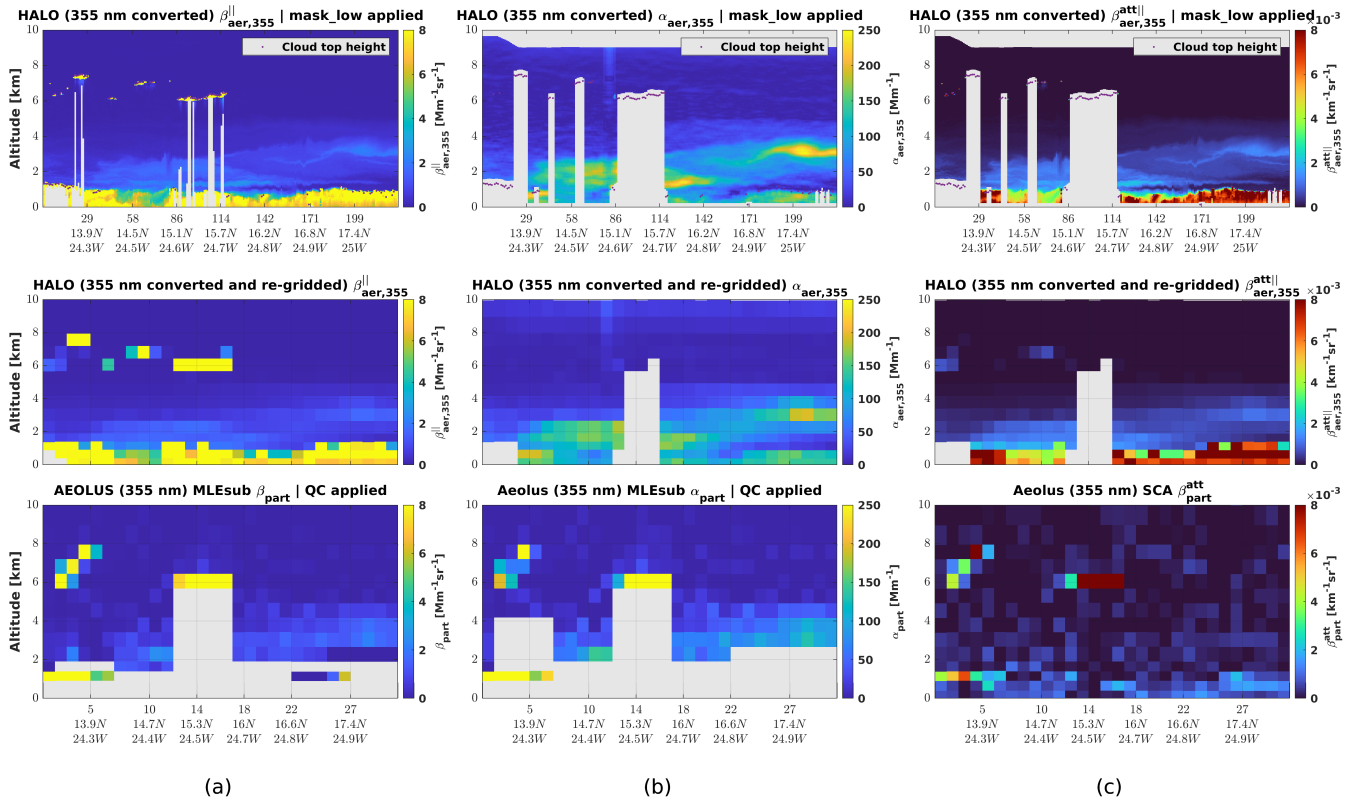

Figure 9. Aeolus MLEsub β_{part} (a), MLEsub α_{part} (b), and SCA $\beta_{\text{part}}^{\text{att}}$ (c) cross section collocated with HALO 355 nm converted products on 16 September 2022.

Figure 10. Two-dimensional histograms of Aeolus versus HALO 355 nm converted and re-gridded products with HALO $\delta_{circ,532}$ as colors (a-c) and with HALO dominant aerosol type as colors (d-f) on 16 September 2022. A logarithmic transformation has been applied to the signals.

The study presents three cross sections of the atmosphere above the Tropical Atlantic as observed by the ALADIN instrument onboard the Aeolus satellite, and reference lidar systems. For the first time, Aeolus aerosol observing capabilities are evaluated with extended tropospheric sections up to 626 km length with small geolocation offset (i.e., less than 6 km) and time offset (i.e., less than 30 minutes). The Aeolus L2A aerosol products at 355 nm retrieved with SCA and MLEsub algorithms have
 435 been compared to independent measurements from the HALO lidar onboard NASA DC-8 aircraft, the 532 nm signal being converted to 355 nm and re-gridded onto Aeolus sampling. In addition, direct profiles above ground-based Raman lidar Polly^{XT} have been analysed.

Despite different geometry (i.e., nadir-viewing angle for HALO, off-nadir $\approx 35^\circ$ for Aeolus) good agreement between the aerosol retrievals is shown for homogeneous, optically thick aerosol layers. The cross-comparison of the MLEsub backscatter
 440 and extinction coefficients for particles with HALO retrievals reveal R^2 scores up to 0.69 and 0.58 respectively. When looking at the particulate attenuated backscatter coefficient derived with SCA algorithm, R^2 scores reach ≈ 0.48 . A good agreement is observed for highly depolarizing aerosol layers classified as pure dust and dusty mix with the HALO dominant aerosol type product, and such for each scene on 09 September 2022, 15 September 2022, and 16 September 2022. Higher deviations are observed for aerosol-free regions of the atmosphere where the SNR is expected to be very low. The study reveals that
 445 the agreement between the Aeolus and reference measurements can be improved when applying scattering ratio threshold in complement to the QC flags in order to focus on cloud free regions of the atmosphere with high SNR and higher aerosol loads (e.g., flagging the bins out of a range 1.2 – 5). This provides further evidence that the SNR and adequate cloud screening approach are important parameters to consider when using Aeolus L2A product for aerosol profiling.

Optical characteristics of marine aerosols and clouds below dust mixture are well captured by Aeolus (e.g., 09 September
 450 2022) suggesting that the UV laser emissions can penetrate enough aerosol layer distributed in irregular shaped particles with linear aerosol depolarization ratio at 532 nm above 0.25. The opposite condition, i.e., diffuse aerosol layer below broken clouds, should be analysed with caution as the low SNR seems not sufficient to trust retrievals of low backscatter coefficient (e.g., 16 September 2022). Spatial extent of aerosol layers such as SAL are clearly visible with L2A MLEsub as the optimal estimation approach helps to smooth signal over consecutive profiles (i.e., the SCA standard concept corresponding to an along-
 455 track averaging of lidar signal resulting in high noise dependency). We then do recommend opting for the MLEsub dataset if focusing on long and homogeneous layers. The SCA algorithm retrievals appears noisier showing higher sensitivity to signal attenuation in low scattering regions of the atmosphere. The SCA also underestimates the particulate attenuated backscatter for both dusty mix and marine regimes. The Aeolus RBS and their in-orbit deviations must be considered with caution as the better optical properties would be obtained when range bin are not encompassing layer edges or complex mixture. We then do
 460 recommend focusing on settings below 1 km thickness when studying vertical sedimentation of aging thin layers. Moreover, the Aeolus signal from scattered or broken clouds should be analysed with caution as cloud echo dilution can be observed when signal averaging includes contribution from the surroundings with lower backscatter signal. The averaging dilution is expected to be more prominent with coarser horizontal resolution BRC of ≈ 90 km. We then do recommend using the sub-BRC level

products when focusing on signal from localized clouds. One should note the negative impact of low SNR below 2 km altitude
465 where the MLEsub products appear to be flagged by the QC, and where the range bins thickness decrease from 750 m to 500
m for the Cabo Verde region.

The present study demonstrates the independent HSRL measurement of aerosol properties such as particle extinction and
backscatter coefficients, even for missions initially designed for winds such as Aeolus. The collocation of the Aeolus data with
the HALO polarization measurements demonstrates the aerosol typing capabilities and provides further evidence of the need
470 for Aeolus-2 to have polarization capabilities. The Aeolus MLEsub extinction is recommended for aerosol layer detection and
both the MLEsub backscatter and SCA particulate attenuated backscatter allow to capture water clouds with strong signals
below dusty mix. The study illustrates how Aeolus is capable of measuring optical properties of aerosols, even for highly
depolarizing particles once correcting the missing cross-polarized signal. This provides support for further development of new
Aeolus product (e.g., co-polarized to total backscatter coefficient using depolarization information from another instrument).
475 The validation of Aeolus L2A SCA and MLEsub products with extended and collocated tropospheric sections with high
spectral resolution lidar also supports first estimation of lower limits for the backscatter detection (e.g., $\approx 1.0 \times 10^{-7} \text{ m}^{-1} \text{ sr}^{-1}$
for dusty mix focusing on quality flagged MLEsub backscatter coefficient for particles, and $\approx 2.0 \times 10^{-4} \text{ km}^{-1} \text{ sr}^{-1}$ for
dust mix focusing on SCA particulate attenuated backscatter). The use of arithmetic mean when re-gridding independent
measurement onto Aeolus sampling is straightforward but one could derive the confidence index as function of SNR, aerosol
480 types detected with ad-hoc classification, or portion of valid measurements considered per Aeolus coarser range bin. Vertical
sampling is a limitation to bear in mind for new missions such as EarthCARE and Aeolus-2; the finer the vertical resolution with
strong signal, the better the measurement will allow analysis of diffuse aerosol plume and mixture where complex atmospheric
processes occur. The importance of a polarization channel for next generation of instrument is also demonstrated as it enables
aerosol typing, which now becomes a major objective for aerosol missions. Finally, it would be beneficial to reproduce the
485 validation of Aeolus L2A product with independent lidar measurements focusing on the early mission period as a significant
signal loss was reported for the ALADIN instrument throughout the satellite lifetime (Lux et al., 2024; Reitebuch et al., 2024).
One would expect higher signal and better performance of the L2A algorithms than for the period September 2022 selected
for this paper. The public release of Aeolus reprocessed dataset labelled Baseline 16 and covering 2018 to 2019 is planned for
2025 and can be used for the study.

490 *Data availability.* Aeolus Baseline 16 L2A data were obtained from the Aeolus-DISC as part of Cal/Val reprocessing activities which
involves TROPOS, DLR, DoRIT, ECMWF, KNMI, CNRS until 31st December 2022, S&T, ABB and Serco. HALO DC-8 data have been
downloaded from <https://www-air.larc.nasa.gov/cgi-bin/ArcView/cpex.2022#NEHRIR.AMIN/> on May 17, 2023. Data of JATAC 2021 and
2022 can be found at <https://earth.esa.int/eogateway/missions/aeolus/data> and <https://askos.space.noa.gr>.

Author contributions. The study was conducted in the frame of Aeolus-DISC as part of L2A processor version 16 development and validation activities. The contributors for L2A SCA and MLE algorithms maintenance and improvement are DT (present), AL (former), TF (former) and AD (former). The operational version of the L2A processor is prepared by DH before deployment at ESA. AN is the principal investigation and technical point of contact for the NASA HALO instrument associated data. MH has provided the estimations of backscatter-related Ångström exponent and extinction-related Ångström exponent measured with Polly^{XT} instrument. This article is part of the special issue «The Joint Tropical Atlantic Campaign (JATAC)». It is not associated with a conference. The paper was written by DT and reviewed internally by Oliver Reitebuch (German Aerospace Center DLR).

Competing interests. The authors declare no competing interests.

Disclaimer. The study includes Aeolus aerosol products prepared by the Aeolus DISC (involving ESA, DLR, DoRIT, ECMWF, KNMI, CNRS until 31st December 2022, TROPOS, S&T, ABB and Serco) and the Payload Data Ground Segment (PDGS) through the reprocessing activities. The corresponding dataset of September 2022 is part of the 4th reprocessing, labelled Baseline 16 and covering July 2019 to April 2023. A first part of this dataset was released to public on May 2024. The Aeolus L2A data are gradually made public since May 2021 through the ESA Aeolus Online Dissemination System ADDF at <https://aeolus-ds.eo.esa.int/oads/access/>. The Python plotting library Matplotlib (Hunter, 2007) has been used for the study as the Bipolar Colormap which can be downloaded from the MATLAB Central File Exchange at <https://www.mathworks.com/matlabcentral/fileexchange/26026-bipolar-colormap>.

Acknowledgements. We thank all previous contributors to the L2A product development and validation from Meteo France CNRM/CNRS (Pierre Flamant, Marie-Laure Denneulin, Mathieu Olivier, Vincent Lever, Pauline Martinet, Hugo Stieglitz, Ibrahim Seck). We acknowledge TROPOS members involved in the Ocean Science Centre Mindelo (OSCM) instrumentation maintenance Ronny Engelmann, Dietrich Althausen and Annet Skupin. We also acknowledge the HALO team for the collection of CPEX-CV dataset as well as the entire CPEX-CV science, instrument, and aircraft operations teams for the successful execution of the CPEX-CV campaign. We also thank Aaron Piña (United States Forest Service USFS) and Edward P. Nowotnick (NASA Goddard Space Flight Center) for their support within the JATAC Campaign.
