**Abstract.** Temperature inversions (TIs) strongly regulate the accumulation and dispersion of air pollutants, yet their nationwide impacts on surface PM<sub>2.5</sub> remain poorly quantified. Here we integrate high-resolution L-band radiosonde profiles with PM<sub>2.5</sub> monitoring data from 2016–2021 to characterize the frequency, ~~strength~~<sup>intensity</sup>, thickness, and diurnal variability of TIs—including surface-based inversions (SBIs) and elevated inversions (EIs)—across mainland China. We show that TIs are pervasive, occurring on average 52% of days, with mean strength of 2.1 °C and thickness of 214 m, and are more common at 08:00 than 20:00. ~~Distinct regional patterns emerge: SBIs dominate in northern China, whereas EIs prevail in eastern China. Overall, SBIs are 1.3 °C stronger than EIs.~~ ~~Distinct regional patterns emerge: SBIs dominate in northern China and are significantly stronger 1.3 °C higher than EIs, whereas EIs prevail in eastern China.~~ TIs intensify seasonal pollution, with 76% of PM<sub>2.5</sub> episodes coinciding with inversion events. SBI strength correlates positively with PM<sub>2.5</sub> concentrations nationwide, while EI parameters show negative associations in eastern and southern regions. These findings reveal the spatiotemporal dynamics of TIs, establish quantitative links to surface pollution, and highlight regionally divergent mechanisms, providing critical insight for air-quality forecasting and targeted emission control.

**Keywords:** Temperature inversion, PM<sub>2.5</sub>, Air pollution, Radiosonde profiles.

## 1 Introduction

Fine particulate matter (PM<sub>2.5</sub>, aerodynamic diameter  $\leq 2.5 \mu\text{m}$ ) is a dominant component of atmospheric aerosols and a key indicator and a primary pollutant of air pollution in China (Liang et al., 2021; Luo et al., 2024; Yan et al., 2023; Zang et al., 2021). Over the past two decades, recurrent severe haze episodes characterized by elevated PM<sub>2.5</sub> levels have imposed substantial public health burdens, including respiratory, cardiovascular, and reproductive impairments, as well as increased cancer risk (Chan and Yao, 2008; Yan et al., 2021; Garcia et al., 2023; Rentschler and Leonova, 2023; Zuo et al., 2023; Chen

et al., 2025). In response, stringent emission control policies since 2013 have markedly improved air quality, with annual mean PM<sub>2.5</sub> concentrations declining from 68  $\mu\text{g m}^{-3}$  in 2013 to 29  $\mu\text{g m}^{-3}$  in 2022 (Meng et al., 2023; Peng et al., 2025; Zou et al., 2025). Nevertheless, seasonal pollution episodes remain acute, particularly in the Beijing–Tianjin–Hebei (BTH) region, where the 2022 annual mean still reached 44  $\mu\text{g m}^{-3}$  (Ministry of ecology and environment the people’s republic of China, 2022), exceeding the World Health Organization’s Stage-1 interim target of 35  $\mu\text{g m}^{-3}$  (WHO, 2021). Growing evidence shows that such extreme events are not solely determined by anthropogenic emissions but are strongly modulated by adverse meteorological conditions, among which temperature inversion (TI) plays a pivotal role (Feng et al., 2020; Morawska et al., 2021; Deng et al., 2022; Shao et al., 2023; Sun et al., 2025).

In meteorology, TI refers to the anomalous increase of temperature with altitude, most frequently observed in the lower troposphere. TIs arise through multiple mechanisms, including nocturnal radiative cooling, warm-air advection, topographic confinement, as well as under specific synoptic conditions such as stationary high-pressure systems (subsidence warming) and frontal zones (Vihma et al., 2011; Kassomenos et al., 2014; Largeron and Staquet, 2016; Xu et al., 2019). Surface-based inversions (SBIs) typically form at night when radiative cooling produces a shallow, stable layer of cold air near the surface, which usually dissipates after sunrise or under strong winds ( $>20 \text{ km h}^{-1}$ ) (Czarnecka et al., 2019). In contrast, elevated inversions (EIs) are often associated with synoptic-scale phenomena. Key driving mechanisms include synoptic-scale warm advection, subsidence within high-pressure systems, and frontal overrunning (Huang et al., 2021; Palarz et al., 2018).

The presence of TI suppresses turbulent mixing, strengthens atmospheric stability, and traps pollutants near the surface (Kahl, 1990; Zhong et al., 2018). Within the boundary layer, this stable stratification creates a pronounced “capping effect” that critically limits vertical pollutant dispersion (Stull, 1988). The resulting suppression of atmospheric pollutant dispersion and transport operates through three interconnected mechanisms. First, the inversion layer itself acts as a meteorological cap, inhibiting vertical mixing and fostering rapid near-surface accumulation of aerosols (Zhong et al., 2017). Second, synoptic conditions conducive to inversion formation—particularly for surface-based inversions—are often accompanied by weak horizontal winds, further restricting advective transport (Yang and Shao, 2021). Third, the persistence of inversions, especially under wintertime high-pressure systems, prolongs pollution episodes over multiple days, allowing progressive buildup of PM<sub>2.5</sub> and compounding air quality deterioration (Feng et al., 2020). Collectively, these processes establish TIs as a pivotal meteorological driver of severe pollution across diverse regions.

Extensive research over the past two decades has examined the characteristics of TIs and their interactions with air pollution (Rendón et al., 2015; Wolf et al., 2014; Wu et al., 2014; Yin et al., 2021). Early studies highlighted their synoptic controls: Milionis and Davies (1992) identified upper-level inversions between 950–800 hPa over Hemsby, UK, primarily associated with subsidence within anticyclonic systems. At a continental scale, Zhang et al. (2011) analyzed radiosonde data from 50 U.S. stations and showed that lower-tropospheric inversions (LTIs) are widespread, with strong zonal wind shear playing a key role in their formation. More recently, advanced remote sensing has enabled quantitative assessment of

63 inversion–aerosol interactions. For example, Liu et al. (2022) combined lidar and radiosonde measurements over the Southern  
64 Great Plains to demonstrate that inversion intensity critically determines the aerosol-trapping capacity of the boundary layer.

65 Nonetheless, most existing studies remain limited to individual cities or specific regions. For example, Wallace et al.  
66 (2009) showed that nocturnal inversions in Hamilton, Canada increased  $PM_{2.5}$  concentrations by 54%, with mobile  
67 observations further revealing the reinforcing role of local topography in inversion formation and pollutant buildup. In China,  
68 Xu et al. (2019) reported that 93% of heavy pollution episodes in Beijing coincided with inversion conditions, while Feng et  
69 al. (2020) found that winter inversions in the Sichuan Basin elevated  $PM_{2.5}$  levels by 64.7% compared with non-inversion days.  
70 Beyond China, Lagmiri and Dahech (2024) identified inversions as the dominant driver of particulate pollution in Cergy-  
71 Pontoise, France, with nearly 80% of  $PM_{10}$  exceedances occurring under inversion conditions persisting 1–3 days in winter.  
72 Structural analyses have also revealed multi-layer inversion systems: Li et al. (2012) described a four-tiered inversion structure  
73 over central China, linking mid-tropospheric inversions to synoptic cold fronts and regional advection, while upper-level  
74 inversions exhibited strong latitudinal dependence.

75 While these studies underscore the critical role of inversions in pollution accumulation, substantial knowledge gaps  
76 remain regarding their nationwide patterns and interactions with  $PM_{2.5}$  across China’s diverse climatic and topographic settings.  
77 The country’s complex geography—spanning plains, basins, and plateaus—produces pronounced regional heterogeneity in  
78 inversion mechanisms and vertical structures (Yang et al., 2025). For instance, the North China Plain is frequently subjected  
79 to strong wintertime SBIs, whereas the Sichuan Basin is characterized by deep, persistent inversions confined by topography  
80 (Guo et al., 2020; Huang et al., 2021; Xu et al., 2021). Such spatial variability drives region-specific impacts on  $PM_{2.5}$   
81 accumulation, underscoring the need for systematic, high-resolution observational analyses. Although Yang and Shao (2021)  
82 documented a nationwide increase in inversion frequency over the past three decades using reanalysis products, the coarse  
83 vertical resolution of datasets such as ERA5 (25 hPa layers) hampers accurate representation of inversion structure. Similarly,  
84 radiosonde-based studies (Guo et al., 2020; Huang et al., 2021; Xu et al., 2021) have provided valuable regional insights but  
85 fall short of offering a comprehensive national-scale assessment of boundary-layer inversions and their impacts on  $PM_{2.5}$   
86 pollution.

87 In this study, we employ high–vertical-resolution radiosonde observations (6–8 m) from 2016 to 2021 to accurately detect  
88 inversion layers and their vertical structures, thereby overcoming the coarse limitations of reanalysis data. By integrating these  
89 measurements with nationwide  $PM_{2.5}$  monitoring records from the Ministry of Ecology and Environment, we systematically  
90 characterize the spatiotemporal distribution of TIs across China, quantify the distinct impacts of SBI and EI on surface  $PM_{2.5}$   
91 concentrations, and establish dynamic relationships between inversion parameters and pollution levels. These findings provide  
92 new mechanistic insight into inversion–pollution interactions and offer scientific support for region-specific air quality  
93 forecasting and management.

95 **2 Study area and Data**

96 **2.1 Study area**

97 Our analysis covers mainland China, a region of vast spatial extent and pronounced physiographic complexity where  
98 monsoonal and continental regimes interact to produce strong environmental heterogeneity. To capture this diversity, we  
99 partition the domain (excluding Hong Kong, Macau, and Taiwan owing to data limitations) into seven regions based on  
100 standard administrative divisions, integrated meteorological characteristics and major urban agglomerations (Fig. 1). The  
101 Northeast (NE)—a traditional industrial base with cold, dry winters—features emissions dominated by coal-fired heating and  
102 heavy industry. North China (NC), including the Beijing–Tianjin–Hebei megacity cluster, is characterized by dense population,  
103 intensive industrial and vehicular activity, and frequent severe haze. The Northwest (NW) comprises plateaus, basins, and  
104 deserts under a continental climate with strong insolation and large diurnal temperature ranges; dust and energy/chemical  
105 sectors are major contributors. East China (EC) and South China (SC) lie in the East Asian monsoon zone and are among the  
106 most economically active regions, influenced by industrial and traffic emissions and regional transport. Central China (CC),  
107 located in the heart of the country, experiences a transitional monsoon climate between the northern subtropical and warm  
108 temperate zones, characterized by a terrain dominated by plains and hills. Pollutants tend to accumulate in basins such as the  
109 Jiangnan–Dongting Basin due to the region’s enclosed topography and stable atmospheric conditions, where they further  
110 combine with polluted air masses transported from the north, resulting in regional and complex air pollution. The Southwest  
111 (SW)—spanning the Tibetan Plateau, the Yunnan–Guizhou Plateau, and the Sichuan Basin—is the most topographically and  
112 climatically diverse, where topographic confinement and local circulations strongly modulate pollution composition and  
113 evolution.

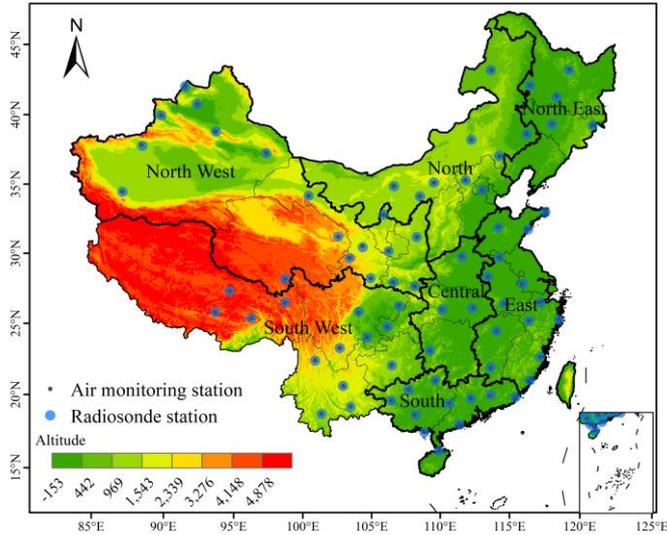

Fig.1 Distribution of 75 radiosonde stations in China. The inset map in the lower right shows the South China Sea Islands.

## 2.2 Data

Radiosonde observations. We use L-band high-resolution sounding data from the operational network of the China Meteorological Administration (CMA). Since nationwide deployment in 2011, the system has routinely operated ~120 radiosonde stations with standard launches at 08:00 and 20:00 Beijing Time (00:00 and 12:00 UTC), with additional warm-season soundings (May–August) to capture monsoon processes (Guo et al., 2016; Yan et al., 2020). The GTS1 digital radiosonde provides vertical profiles of temperature, pressure, humidity, wind speed, and direction from the surface (0 m AGL) to ~30 km, with 5–8 m nominal vertical resolution (sampling frequency 1.2 s). By integrating in-situ observations from the co-located surface weather station as the initial record, the valid bottom height for all profiles is strictly maintained at 0 m. Independent assessments indicate temperature errors <0.1 K in the troposphere and data quality comparable to internationally recognized radiosondes within the planetary boundary layer (Ma et al., 2010). These measurements have been widely applied to studies of cloud microphysics, PBL height, and inversion detection, and as inputs to numerical weather prediction and atmospheric composition research (Li et al., 2019; Zang et al., 2017; Zhang et al., 2020). For this study (2016–2021), we applied routine quality control to remove obvious temperature/height outliers and used the full-resolution vertical profiles to identify inversion layers and derive their properties.

Surface PM<sub>2.5</sub> monitoring. Hourly PM<sub>2.5</sub> concentrations were obtained from the national air-quality monitoring network operated by the China National Environmental Monitoring Centre (CNEMC; real-time platform: <https://www.cnemc.cn/en/>) (Miao et al., 2020; Yan et al., 2020). As of 1 March 2022, the network comprised 2,026 stations with dense coverage in eastern

带格式的：两端对齐

133 urban clusters and relatively sparse representation in western high-altitude regions. To match radiosonde stations with PM<sub>2.5</sub>  
 134 monitors, we used a distance threshold method with a 10 km search radius. This approach identified 75 valid station pairs,  
 135 balancing spatial representativeness and sample size (Fig. 1). The 10 km threshold avoids underrepresentation from smaller  
 136 radii and minimizes spatial error from larger distances, representing the point where further increases yield diminishing returns  
 137 in matches (the distribution of original sites and the screening method are referenced in Figs S1 and S2.). For temporal  
 138 alignment with the soundings, hourly PM<sub>2.5</sub> records were extracted around 08:00 and 20:00 BJT. Basic completeness checks  
 139 and standard plausibility screening were applied before analysis.

140 Rationale for integration. The combination of meter-scale-resolution vertical thermodynamic profiles with collocated  
 141 surface PM<sub>2.5</sub> enables a consistent, observation-based assessment of inversion frequency, intensity, and thickness—and their  
 142 diurnal and regional variability—while overcoming the coarse vertical structure inherent in reanalysis products (Li et al., 2019;  
 143 Yan et al., 2020; Zhang et al., 2020)

### 144 3 Method

145 The sounding data underwent manual quality control to identify and systematically remove obvious errors in temperature and  
 146 height measurements. Raw temperature profiles were first interpolated using cubic splines to ensure vertical continuity. TIs  
 147 were then identified by applying a first-derivative algorithm to the smoothed profiles (Kahl, 1990; Serreze et al., 1992). Each  
 148 profile was scanned upward from the surface; layers exhibiting a positive vertical temperature gradient were classified as  
 149 inversion layers, while those with negative gradients were considered non-inversion zones. The base height of an inversion  
 150 layer was defined as the lowest altitude at which temperature began to increase with height, and the top height was identified  
 151 as the point where the gradient reverted to negative. Following Kahl et al. (1996), three fundamental TI parameters were  
 152 derived: inversion thickness ( $\Delta H$ ), inversion strength ( $\Delta T$ ), inversion frequency ( $F_{TI}$ ). They are defined as:

$$153 \quad \Delta H = H_t - H_b \quad (1)$$

$$154 \quad \Delta T = T_t - T_b \quad (2)$$

$$155 \quad F_{TI} = N_{TI}/N \quad (3)$$

$$156 \quad F_{SBI} = N_{SBI}/N \quad (4)$$

$$157 \quad F_{EI} = N_{EI}/N \quad (5)$$

158 where  $H_t$  and  $H_b$  represent the top and bottom heights of the TI layer respectively;  $T_t$  and  $T_b$  represent the temperatures  
 159 at the top and bottom respectively;  $N$  represents the total number of detections,  $N_{TI}$  represents the number of detections  
 160 where TI occurs, and  $N_{SBI}$  and  $N_{EI}$  represent the number of detections where SBI and EI occur respectively.

161 To mitigate false positives from small-scale turbulence (e.g., "sawtooth" noise in balloon-borne measurements),  
 162 thresholds for  $\Delta H$  and  $\Delta T$  were imposed per established practices (Guo et al., 2020; Kahl, 1990). A layer was classified as

163 a valid TI only if  $\Delta H \geq 100$  m and  $\Delta T \geq 0.5^\circ\text{C}$ ; otherwise, it was discarded. Non-inversion layers embedded within broader  
164 TIs were permitted, provided the overarching TI met these criteria. The temperature profile was scanned upward from the  
165 surface, and the first continuous layer satisfying  $\Delta H \geq 100$  m and  $\Delta T \geq 0.5^\circ\text{C}$  was identified as the inversion for that  
166 sounding. To specifically target thermodynamic processes influencing surface air quality, this study considers only inversion  
167 layers with a base height  $H_b \leq 2000$  m. Inversion can also be classified into SBI and EI based on the base height. When  $H_b$   
168  $< 100$  m, it is called Surface-based inversions (SBIs); when  $100 \text{ m} < H_b \leq 2000$  m, it is called Elevated inversions (EIs).  
169 For additional validation at different thickness thresholds, please refer to supplementary Figs S18-S20. Theoretical calculations  
170 indicate that each station should have a total of 4384 soundings at 12-hour intervals from 2016 to 2021. In practice, however,  
171 data omissions occurred due to various factors, resulting in an average missing rate of 3.2% for TI data in the final statistics.

172 According to China's National Ambient Air Quality Standards (GB3095-2012), the standard for a pollution event is based  
173 on a daily mean  $\text{PM}_{2.5}$  concentration exceeding  $75 \mu\text{g m}^{-3}$ . In this study, to align with the instantaneous radiosonde observations  
174 at 08:00 and 20:00 BJT, we applied this concentration threshold  $75 \mu\text{g m}^{-3}$  to the hourly  $\text{PM}_{2.5}$  data to identify pollution events  
175 corresponding to the sounding times.  $\text{PM}_{2.5}$  concentrations are further classified into six categories: Excellent:  $0\text{-}35 \mu\text{g m}^{-3}$ ;  
176 Good:  $35\text{-}75 \mu\text{g m}^{-3}$ ; Light pollution:  $75\text{-}115 \mu\text{g m}^{-3}$ ; Moderate pollution:  $115\text{-}150 \mu\text{g m}^{-3}$ ; Severe pollution:  $150\text{-}250 \mu\text{g m}^{-3}$ ;  
177 Extreme pollution:  $>250 \mu\text{g m}^{-3}$ . To align with the spatiotemporal characteristics of the radiosonde data, the hourly  $\text{PM}_{2.5}$  data  
178 were processed into two time periods corresponding to the radiosonde observations: 08:00 and 20:00 Beijing Time.

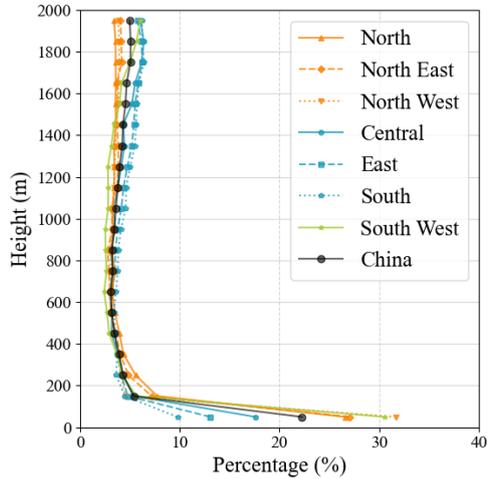

## 179 4 Results and Discussions

### 180 4.1 Spatiotemporal distribution of atmospheric temperature inversions in China

181 The base height of TI sets the effective lid for vertical pollutant dispersion. To resolve its vertical structure within the boundary  
182 layer, we quantified the vertical distribution of inversion events. This is defined as the percentage of the total number of  
183 inversion events falling within each 100-m height bin from the surface to 2 km (Fig. 2). A distinct non-linear profile emerges:  
184 ~~the~~The TI proportion peaks sharply in the lowest 0–100 m bin, which comprises exclusively SBIs and accounts for 22.2% of  
185 all inversion events. This peak is followed by a rapid decline to a minimum of 3.1% at 600–700 m, and then a gradual recovery  
186 to 5.1% at 1800–1900 m—i.e., a “rapid decline, then slow recovery” with height.

187 Marked regional contrasts accompany this vertical pattern. In the near-surface layer (0–100 m, i.e., the SBI), the Northwest  
188 exhibits the highest TI proportion 31.6%, followed by Southwest 30.5%. In comparison, Central, East, and South China show  
189 lower near-surface SBI proportions, with South China the lowest 9.8%. The pattern reverses aloft: for elevated inversions in  
190 the 1000–2000 m layer, South China records the highest proportion 56.0%, whereas northern regions are much less affected.  
191 Taken together, intense near-surface trapping by SBIs preferentially occurs over inland northern and southwestern China, while  
192 EIs are more common and reach higher altitudes in the southeastern coastal belt. A potential driver of this dipole is the diurnal

193 temperature range (DTR): larger DTRs over inland regions enhance nocturnal radiative cooling, favoring strong SBIs; weaker  
 194 DTRs in maritime-influenced southeastern areas favor synoptic processes that produce EIs.<sup>22</sup>  
 195

 198

199 **4.1.1 Inversion frequency**

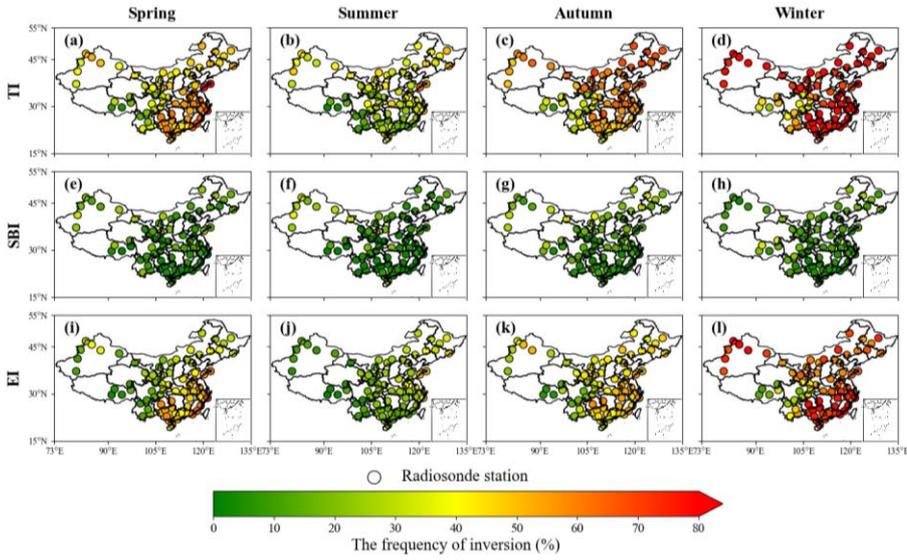

200 Figure 3 maps the spatial and seasonal variability of TI frequency over China (2016–2021), revealing pronounced regional  
 201 heterogeneity. High TI occurrence is concentrated along the coasts (East and South China) and across northern China  
 202 (Northeast, North, Northwest), yielding a national annual mean of 54.9%. Regionally, Northeast China records the highest  
 203 frequency (59.5%), whereas the Southwest exhibits the lowest (31.3%; Table 1). The suppressed occurrence in the Southwest  
 204 likely reflects two factors: (i) in the Sichuan Basin, the dominant signal is lower-tropospheric inversions (LTIs) which typically  
 205 occur at altitudes of 2,200–3,400 m—well above the 0–2,000 m height range examined in this study—resulting in their  
 206 exclusion from our frequency statistics, and (ii) plateau climate conditions—high elevation, strong solar radiation, low air  
 207 density, and frequent strong winds linked to the westerly jet—enhance turbulent mixing and disrupt inversion persistence (Feng  
 208 et al., 2020; Schiemann et al., 2009). National averages by type indicate SBIs ~13% and EIs ~43% annually (Figs. 4d, 4g). EIs  
 209 dominate total events nationally. The two inversion types exhibit contrasting geography: SBIs cluster over northern China  
 210 (Northeast, North, Northwest) with annual frequencies of 14.9–16.1%, whereas EIs prevail across the southeastern coastal and  
 211 central regions (South, East, Central China), averaging 48.1% and peaking at 51.6% in East China. This spatial dipole aligns  
 212 with previous radiosonde climatologies, which report more frequent SBIs in northern/western China and EI dominance in the  
 213 south and east (Huang et al., 2021). A persistent “east-high, west-low” gradient is also evident. One contributing factor is the

214 fixed launch time relative to local solar time: China spans roughly five time zones, so the 08:00 BJT sounding corresponds to  
215 ~05:00 local time in the far west, when nocturnal inversions may not yet have fully developed, biasing frequencies lower there.

216 Figure 4a shows pronounced seasonality in TI occurrence. The highest monthly means occur at 08:00 BJT in January  
217 (84.0%) and at 20:00 BJT in December (68.8%), whereas minima appear in June (31.9%) and August (32.0%). SBI occurrence  
218 shows relatively high frequencies (>24%) in February, March, September, and October, whereas EI frequency exhibits a sharp,  
219 single peak in January (75.2%). Seasonal contrasts are stark: inversions are most frequent in the cold season and relatively rare  
220 in the warm season. The spatial footprint of inversion-prone areas expands westward from summer to winter: in summer, only  
221 the Northeast exceeds 40%, and the Southwest falls to 17.5%; in winter, all regions except the Southwest surpass 70%, reaching  
222 80.5% in the Northeast. SBIs and EIs share this seasonal phasing—winter maxima, summer minima—consistent with longer  
223 winter nights that enable sustained radiative cooling and stronger stability.

224 Further analysis (Figs. S5, S6 and 4a) shows a robust dawn–dusk asymmetry: inversions are more likely to occur at 08:00  
225 BJT across all regions and seasons, with daytime launches accounting for 62% of all TI detections. The contrast is strongest  
226 in summer, when 08:00 inversions comprise 71% of events, and weaker in winter (57%). This seasonal modulation reflects  
227 differences in solar forcing. In summer, long days and short nights curtail both the formation window and stability of inversions:  
228 with sunrise near 05:20 BJT, 2–3 hours of insolation have already eroded the nocturnal layer by 08:00, and by 20:00 roughly  
229 12 hours of high-angle solar heating have largely dissipated residual stability—yielding a 26.4% frequency gap between the  
230 two launch times. In winter, short days and long nights promote the development of deeper and more persistent inversions  
231 through enhanced radiative cooling. With sunrise as late as around 07:20 BJT, the weak early-morning insolation preceding  
232 the 08:00 sounding is insufficient to dissipate the TI layer significantly. Furthermore, the wintertime atmosphere is significantly  
233 drier (Fig. S7), which minimizes downward longwave radiation and thereby maximizes the efficiency of nocturnal surface  
234 cooling. The subsequent ~10 hours of low-angle daylight provide insufficient thermal energy to significantly disturb the stable  
235 surface layer before 20:00. Consequently, the 08:00–20:00 frequency difference contracts to 14.8% in winter.

#### 246 4.1.2 Inversion strength

247 Among the key TI parameters, strength exerts first-order control on pollutant dispersion. Spatially, TI strength is greater over  
 248 inland northern regions than over southern and eastern coasts (Fig. 5; Table 1): the Northwest has the highest annual mean  
 249 (2.67 °C), whereas the East is lowest (1.86 °C). Extremes span 4.69 °C in the Southwest to 1.67 °C in the East. Seasonally, TI  
 250 strength peaks in winter (2.44 °C), weakens in spring and autumn (both ~2.10 °C), and is lowest in summer (1.53 °C) (Fig. 5).  
 251 Monthly values maximize in February (2.73 °C) and minimize in June (1.23 °C) (Fig. 4b). By inversion type, SBIs are  
 252 consistently stronger than EIs: peak intensities reach 4.45 °C (SBI) versus 2.11 °C (EI) (Figs. 4e, 4h). Correspondingly, annual  
 253 means rank SBI (3.02 °C) > all TI (2.13 °C) > EI (1.76 °C). The strongest seasonal maxima occur in winter in the Northwest  
 254 for both overall TI (2.78 °C) and SBI (4.88 °C), while EI intensity peaks in winter in the South (2.43 °C). Notably, winter SBI  
 255 strength exceeds EI by more than a factor of two. Geographically, SBI intensity varies substantially—annual means in northern  
 256 and northwestern China are over twice those in the south—whereas EI strength is comparatively uniform, ranging from 1.63 °C  
 257 (North/Northeast) to 1.93 °C (South), a spread of only 0.30 °C. Diurnally, TI, SBI, and EI intensities are generally higher at  
 258 08:00 BJT than at 20:00 (Figs. 4b, 4e, 4h). EI shows a regional reversal: daytime -stronger in the Northeast/North, but  
 259 nighttime -stronger elsewhere. The maximum values by category occur at 08:00 in the Northwest for all TI (2.81 °C), 08:00 in  
 260 the North for SBI (4.30 °C), and 20:00 in the South for EI (2.02 °C) (Tables S2, S3).

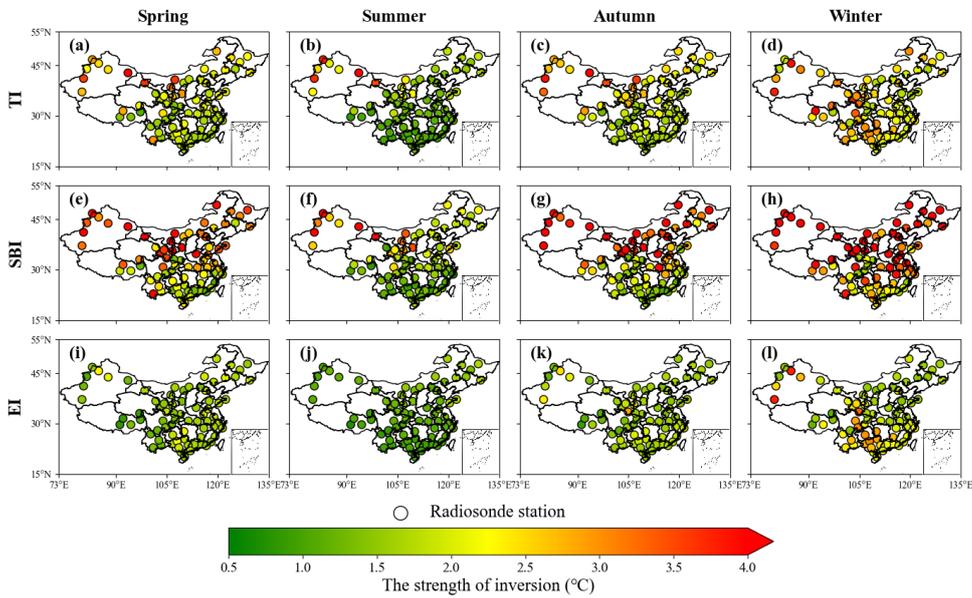

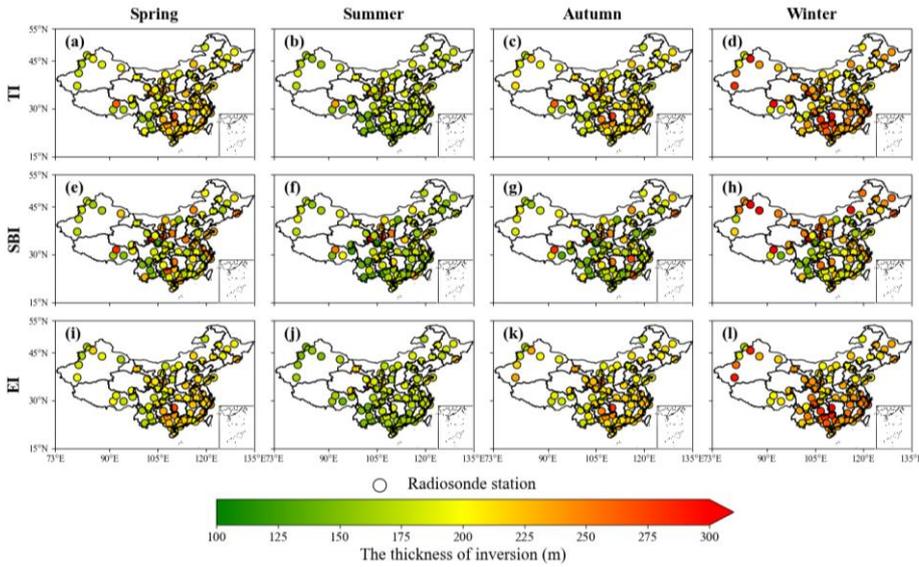

Fig.5 Spatial and seasonal distribution of inversion strength for different types of inversions.

#### 4.1.3 Inversion thickness

Seasonal and regional patterns of inversion thickness for all TIs, SBIs, and EIs are shown in Figure 6 and summarized in Table 1. Across the 75 radiosonde stations, the annual mean thickness is 214 m. Layers sampled at 08:00 BJT are generally thicker than those at 20:00 BJT by about 40 m, consistent with the diurnal phasing of inversion intensity. Thickness varies markedly by season, maximizing in winter (231 m; Fig. 6d) and minimizing in summer (179 m; Fig. 6b). Monthly evolution follows a pronounced “V” shape (Fig. 4c), with a January peak of 243 m. By type, EIs are systematically thicker than SBIs, with annual means of 216 m and 201 m, respectively. Both exhibit winter maxima and summer minima. At 08:00, EI and SBI each display a clear “V”-shaped monthly cycle, whereas at 20:00 their behavior diverges: SBI thickness varies only modestly, while EI thickness remains comparatively stable across months (Figs. 4f, 4i). Spatially, TIs are notably thicker in the eastern and southern regions compared to the northern and western inland areas. Specifically, the average thickness in East, South, and Central China is 223 m, whereas it is 209 m in Northeast, North, and Northwest China. South China shows the largest annual mean thickness (231 m), exceeding the national mean, whereas the Southwest has the thinnest layers (202 m). This pattern aligns with the regional predominance of inversion types: thicker EIs prevail in the eastern/southern regions, while thinner SBIs are more common in the western/northern regions. The lower overall inversion frequency in the Southwest, combined with the intrinsic thickness contrast between EI and SBI, further contributes to these regional differences. Additionally, we

280 discussed the scenario where the lapse rate ( $\Delta T/\Delta H$ ) was used as a proxy for inversion strength, as elaborated in supplementary  
 281 Fig. S16, S17 and Table. S4.  
 282

283

## 286 4.2 The correlation between temperature inversion and PM<sub>2.5</sub>

### 287 4.2.1 Statistical relationship between temperature inversion and PM<sub>2.5</sub> pollution events

288 We quantified the linkage between TIs and PM<sub>2.5</sub> pollution by comparing the share of polluted days under inversion versus  
 289 non-inversion conditions in each region (Table 2). At 08:00 BJT, a strong association emerges nationwide: co-occurrence rates  
 290 span 84.6% in the Northeast (NE) to 62.9% in the Southwest (SW), indicating that morning pollution accumulation is  
 291 substantially conditioned by inversions, with northern regions particularly sensitive—consistent with their higher prevalence  
 292 of SBIs. By contrast, at 20:00 BJT the TI–PM<sub>2.5</sub> coupling weakens markedly; the SW shows the lowest overlap, with only  
 293 27.7% of pollution events coinciding with inversions. This pronounced diurnal asymmetry suggests distinct formation regimes:  
 294 daytime/morning pollution is frequently meteorology-limited by inversion trapping, whereas evening pollution is more  
 295 strongly governed by emission timing and chemical processes than by boundary-layer stability.

Table 2. Frequency statistics of TI corresponding to PM<sub>2.5</sub> pollution events in seven regions of China from 2016 to 2021.

Region	BJT 08:00				BJT 20:00			
	Pollution	Inversion	No-inversion	Inversion proportion	Pollution	Inversion	No-inversion	Inversion proportion
Central	1818	1489	329	81.9%	1713	1027	686	60.0%
East	3239	2672	567	82.5%	3004	1910	1094	63.6%
North	1749	1394	355	79.7%	1433	773	660	53.9%
North East	1072	907	165	84.6%	709	480	229	67.7%
North West	5409	4443	966	82.1%	4734	2299	2435	48.6%
South	1194	891	303	74.6%	881	464	417	52.7%
South West	2523	1586	937	62.9%	2186	608	1578	27.7%

300

301 Figure 7a reveals strong seasonal heterogeneity. Winter registers the most pollution events (17,540), exceeding spring, autumn,  
302 and summer by factors of 2.7, 3.2, and 13.8, respectively. TIs substantially amplify this seasonal contrast: relative to no-  
303 inversion conditions, the probability of a pollution event rises by +52% in winter, +34% in autumn, +10% in spring, and is  
304 negligible in summer. The muted summer response likely reflects a shift toward ozone-dominated chemistry, weakening the  
305 coupling between PM<sub>2.5</sub> and inversion dynamics. Figure 7b shows that TIs not only increase occurrence but also severity—  
306 especially in winter—doubling extreme events (Level 4: 2% → 4%) and raising severe events (Level 3) by 3 percentage  
307 points (15% → 18%). These observations are consistent with the inversion-driven explosive growth conceptual model for  
308 PM<sub>2.5</sub> (Zhong et al., 2017, 2018) and with the view that extreme haze is tightly linked to inversion meteorology (Yang and  
309 Shao, 2021). Autumn TIs exhibit a similar but weaker intensification (+3% in moderate/severe categories), whereas spring and  
310 summer TIs chiefly affect lower-severity bins. Collectively, the results establish TIs as a critical wintertime meteorological  
311 driver of both the frequency and intensity of haze in China.

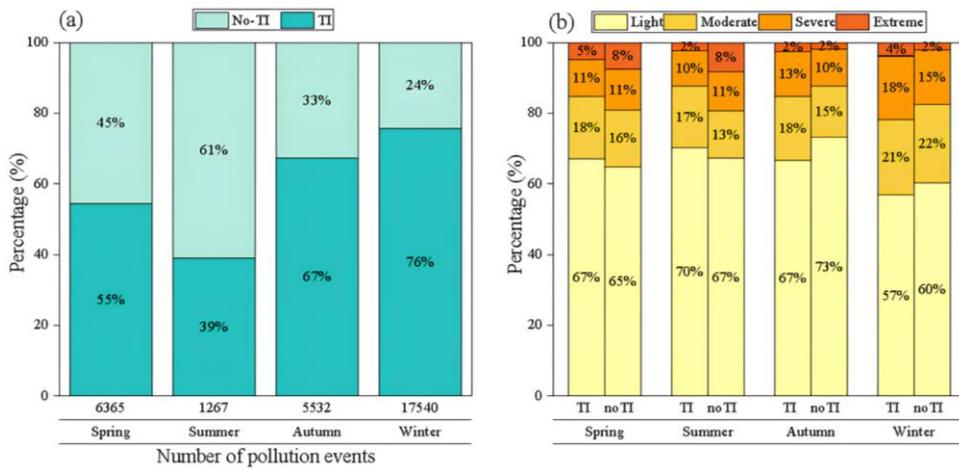

Fig. 7 (a) Frequency of inversion occurrence during polluted periods and (b) distribution of pollution levels in China (2016–2021).

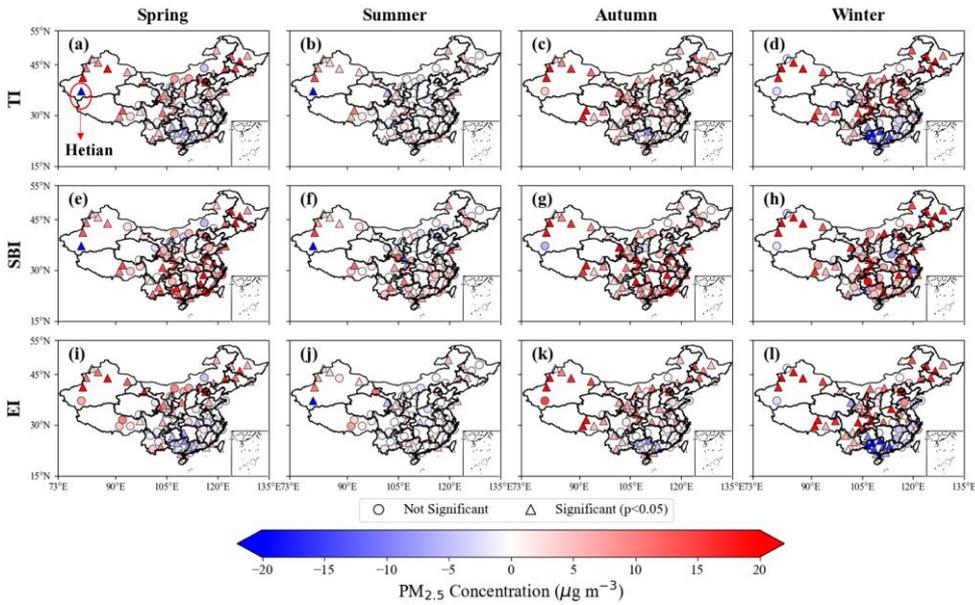

#### 4.2.2 Impacts of different TI types on PM<sub>2.5</sub> concentrations

We quantify inversion impacts by contrasting the daily mean PM<sub>2.5-2.5</sub> concentrations under inversion and non-inversion conditions, with statistical significance assessed using two-sample t-tests (Fig. 8). The time-resolved analyses for 08:00 and 20:00 BJT are shown in Figs. S12 and S13. In eastern China, results broadly align with Shao et al. (2023): PM<sub>2.5</sub> increases significantly under inversions in the Northeast (NEC) and North China (NC), whereas South China (SC) exhibits significant decreases. In western China, most stations also show PM<sub>2.5</sub> enhancements during inversions, with a notable exception at Hetian (southern Xinjiang), where spring–summer concentrations decline significantly (Figs. 8a, 8b). This anomaly likely reflects the dust-dominated composition of PM<sub>2.5</sub> (>90%) and frequent spring–summer dust storms near the Taklamakan Desert; strong winds that accompany dust events are unfavorable for inversion formation, rendering dust outbreaks and inversion episodes largely mutually exclusive (Aishajiang et al., 2020). Consequently, during inversion periods, the dominant dust component is largely absent, yielding lower PM<sub>2.5</sub>.

Disaggregating by inversion type reveals fundamentally different mechanisms. Surface-based inversions (SBIs) robustly increase PM<sub>2.5</sub> across most regions—especially in winter and autumn (Figs. 8g, 8h)—consistent with nocturnal radiative cooling that produces a shallow, stable layer, suppresses vertical mixing, and accelerates near-surface accumulation (Stull, 1988; Zhong et al., 2017). The amplification in northern winters reflects longer nights and stronger surface cooling. By contrast, elevated inversions (EIs) exhibit spatially variable effects: they enhance PM<sub>2.5</sub> in NEC, NC, and Northwest China (NWC), but reduce concentrations in SC. This pattern supports the hypothesis that EIs can inhibit pollutant transport (Yang and Shao, 2021): in SC, EIs often accompany synoptic subsidence or warm advection, establishing a capping layer that limits vertical exchange and isolates the region from northerly inflow. Such a transport-suppression mechanism is less relevant in northern

设置了格式: 下标

333 China, where local emissions dominate. Diurnal contrasts further modulate these responses: morning (08:00) inversions  
 334 generally exert stronger effects than evening (20:00) inversions, particularly in NWC (Figs. S12, S13). Occasional nighttime  
 335  $PM_{2.5}$  decreases under SBIs are observed at some NC/NEC stations, but these changes are not statistically significant.  
 336

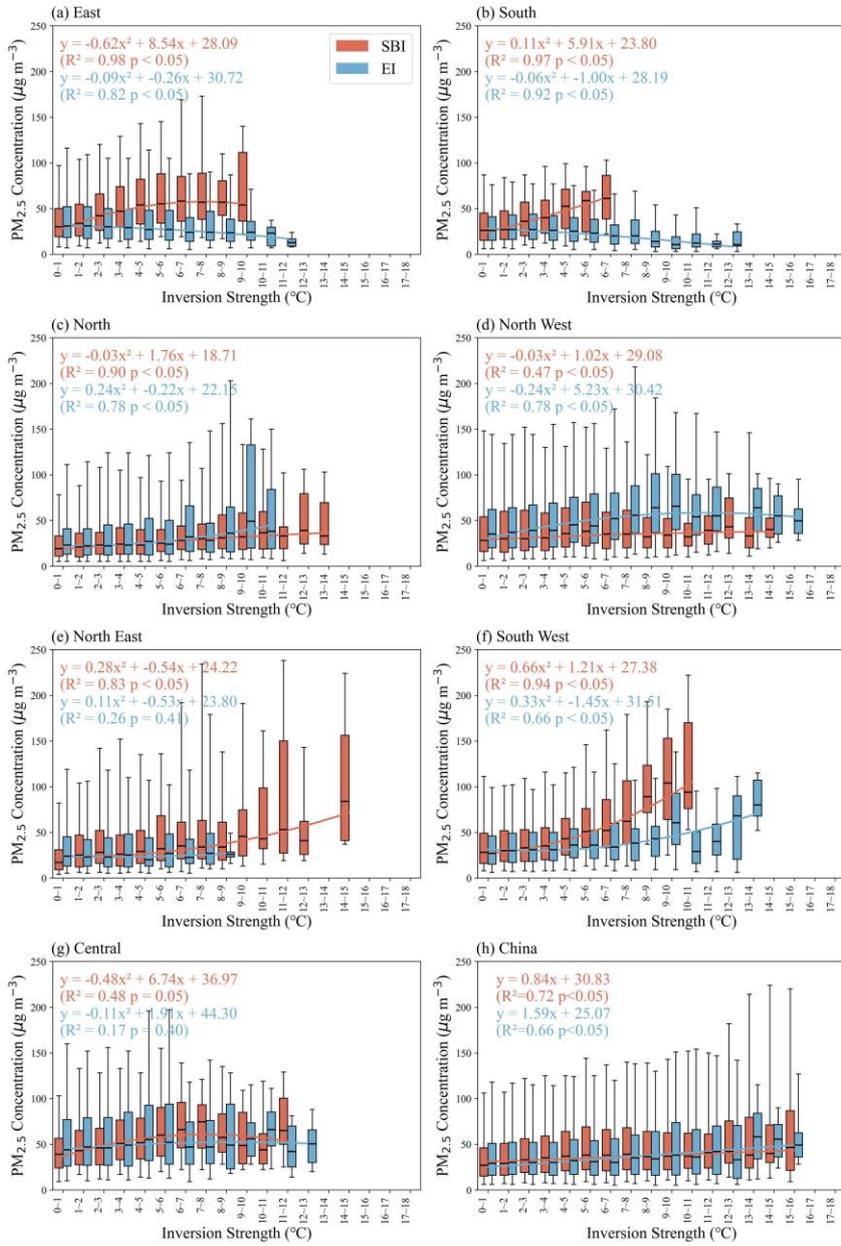

337  
 338 Fig.8 Distribution of  $PM_{2.5}$  concentration differences with and without TI. The larger circle indicates significance at the 95% level ( $t$ -test)  
 339

340 We quantified  $PM_{2.5}$  responses to inversion parameters (strength, thickness) at 75 stations. Nationwide,  $PM_{2.5}$  rises near-  
 341 linearly with inversion strength for both SBIs and EIs (Fig. 9h): below 8 °C, SBIs exert the stronger effect; above 8 °C, EIs  
 342 become more influential. Regionally, four response regimes emerge: Northern Inland China, Southeastern Coastal China,  
 343 Central China, and Southwestern China. In EC/SC, SBI intensity correlates positively with  $PM_{2.5}$  ( $R^2 > 0.9$ ), whereas EI  
 344 intensity correlates negatively ( $R^2 > 0.8$ ); SBI strengths there seldom exceed 10 °C, far weaker than inland values. In NEC/NC,  
 345 SBI strength can exceed 14 °C and is strongly coupled to  $PM_{2.5}$ . EI effects are mixed: NC shows a monotonic increase in  $PM_{2.5}$   
 346 with EI strength; NWC peaks at 10.9 °C (58.9  $\mu g m^{-3}$ ) then declines; NEC shows no significant correlation. In the SWC, both  
 347 SBI and EI display a parabolic relationship with  $PM_{2.5}$ , with SBI exerting the larger enhancement (correlation up to 0.94). In  
 348 Central China, overall fits are poor/non-significant, likely reflecting (i) the limited sample (four stations) and (ii) the region's  
 349 role as a convergence zone receiving substantial inflow from surrounding regions—regional transport contributes >65% to  
 350  $PM_{2.5}$  in cities such as Wuhan (Yu et al., 2020).

351 By contrast, inversion thickness shows a much weaker and less uniform association with  $PM_{2.5}$  (Fig. S14). SBI thickness

域代码已更改

352 is generally positively correlated with  $PM_{2.5}$  (except in NEC). For EI, significant thickness– $PM_{2.5}$  relationships appear only in  
353 NEC and NWC ( $R^2 = 0.86$  and  $0.92$ , respectively); elsewhere, EI thickness exerts negligible influence. Together, these results  
354 establish inversion strength—not thickness—as the dominant predictor of  $PM_{2.5}$  accumulation (Fig. 9 vs. Fig. S14). Thickness  
355 primarily defines the volume of the trapping layer: a deep but weak inversion can be eroded by mechanical turbulence more  
356 readily than a shallow but intense one. This mechanism ensures that a stronger temperature gradient yields greater static  
357 stability and more effective suppression of turbulent mixing (Liu et al., [2022](#)).

358

359 Fig.9 Fitting relationship between inversion strength and PM<sub>2.5</sub> concentration across seven regions of China from 2016 to 2021. The ends of

360 the boxes, the ends of the bars, and the short line across each box represent the 25th and 75th percentiles, the 5th and 95th percentiles, and

361 the median, respectively. Each strength interval contains a sample size  $\geq 10$ .

## 362 5 Conclusions

363 Temperature inversions (TIs) are widely recognized as a key meteorological regulator of near-surface  $PM_{2.5}$ , yet their  
364 nationwide behaviour and impacts have remained incompletely characterized. Leveraging high-vertical-resolution radiosondes  
365 from 75 stations (2016–2021) and collocated surface  $PM_{2.5}$ , we provide an observation-based assessment of inversion  
366 frequency, intensity, thickness, and diurnal variability across China, and quantify how distinct inversion types modulate  
367 pollution accumulation.

368 First, TIs are pervasive: the national annual means are 51.8% for frequency, 2.13 °C for strength, and 214 m for thickness.  
369 Strong regional heterogeneity emerges. SBIs occur more frequently and are substantially stronger over inland northern regions  
370 (annual mean 3.02 °C), whereas EIs prevail along the southeastern coast and are thicker (e.g., 235 m in Central China; 227 m  
371 in South China). Low-level inversions are comparatively rare in the Southwest. Diurnally, inversions are more frequent,  
372 stronger, and thicker at 08:00 BJT than at 20:00, with the SBI day–night contrast muted in summer and amplified in winter—  
373 consistent with radiative control. Second, TIs materially elevate winter haze risk. Relative to non-inversion conditions, the  
374 probability of a pollution event increases by 52% in winter, and the share of extreme events doubles, establishing TIs as a first-  
375 order meteorological driver of both frequency and severity of winter haze in China. Third, the type of inversion matters. SBIs  
376 robustly enhance  $PM_{2.5}$  across most regions, reflecting efficient near-surface trapping under nocturnal stability. EIs show  
377 regionally divergent behaviour: they enhance  $PM_{2.5}$  in the north and northwest but are negatively associated with  $PM_{2.5}$  in the  
378 east and south, consistent with a transport-inhibition mechanism that limits northerly inflow under subsidence/warm-advection  
379 regimes. Fourth, inversion strength is the dominant predictor of  $PM_{2.5}$  accumulation, while thickness plays a secondary, region-  
380 dependent role. Nationally,  $PM_{2.5}$  increases near-linearly with strength for both SBI and EI; below 8 °C SBI effects dominate,  
381 whereas above 8 °C EI effects strengthen. Thickness is generally weakly correlated with  $PM_{2.5}$ , except in select regions (e.g.,  
382 NEC/NWC for EI), underscoring that static stability (temperature gradient) governs ventilation more directly than layer depth.

383 These findings offer concrete avenues for improving air pollution forecasting. (i) Improving the vertical resolution and  
384 the predictive skill of TIs in numerical models could enhance the forecast of air pollution events, particularly in winter. (ii)  
385 Region-specific strategies are warranted: curbing evening–night emissions and promoting nocturnal ventilation are likely most  
386 effective where SBIs dominate (northern basins/plains), whereas transport management and synoptic-regime awareness may  
387 be more impactful in the southeast where EIs can isolate the boundary layer from upwind inflow. (iii) The observed diurnal  
388 asymmetry suggests targeted mitigation during windows of maximum trapping (pre-sunrise to morning transition).

389 Our assessment remains limited by sparser coverage over plateau terrain and the lack of vertical  $PM_{2.5}$  profiles, which  
390 constrains diagnosis of aerosol layering and entrainment. Future work should augment radiosondes with Raman/HSRL lidar,  
391 UAV or aircraft soundings, and assimilate inversion-aware stability metrics into kilometre-scale chemical transport models;  
392 leverage geostationary multi-sensor diurnal sampling to resolve inversion evolution; and evaluate co-trends among inversions,

393 emissions, and climate-driven shifts in nocturnal cooling and synoptic patterns. These steps will sharpen causal attribution of  
394 TI–pollution coupling and strengthen the forecast-to-policy pipeline for region-tailored air-quality management.

395

396 *Data availability.* The radiosonde data used in this study are available from the China Meteorological Administration (CMA).  
397 The hourly ground-level PM<sub>2.5</sub> concentration data can be obtained from the China National Environmental Monitoring Centre  
398 (CNEMC; real-time platform: <https://www.cnemc.cn/en/>).

399
