**Abstract.** Quantifying environmental radiation dose rates is an essential step in age calculation using trapped charge dating methods. A means of rapid dose rate estimation would therefore be useful for a variety of reasons, especially in contexts where

10 rapid equivalent dose estimates are available. For instance, for informing sampling strategy, providing initial age estimates, or supporting portable luminescence studies. However, high-precision methods often used ~~for calculating~~ to calculate dose rates are typically time consuming and expensive and are impractical for such 'range-finder' applications. Portable X-ray fluorescence (pXRF) offers a rapid means of measuring the ~~p~~Potassium (K) concentration of sediment, although the other radionuclides typically used to calculate dose rates, ~~U~~Uranium (U) and ~~T~~Thorium (Th), fall beneath its detection limits at the

15 quantities at which they are usually present in sediments. In this study, we investigate whether pXRF measurements of K concentration alone can be used to accurately estimate total environmental dose rates. A large, global ~~training~~ dataset of 1473 radionuclide samples is used to generate a set of ~~linear regression~~ relationships between (1) K concentration and external beta dose rate; (2) external beta and gamma dose rates; and (3) external gamma and alpha dose rates. We test the utility of these relationships by measuring the K contents of 67 sediment samples with independent, high-precision radionuclide data from a

20 variety of contexts using pXRF. The resulting K concentrations are then converted to external dose rate estimates using ~~the training~~ ~~these~~ equations. A simplified set of attenuation parameters are used to correct infinite matrix dose rate estimates, and these are combined with cosmic ray and internal contributions to rapidly calculate total environmental dose rates for a range of theoretical, common luminescence-dating scenarios (such as 180–250  $\mu\text{m}$  quartz that has undergone etching). Results show that pXRF can accurately measure K concentrations in a laboratory setting. The ~~training-regression~~ equations can predict

25 external beta dose rates ~~accurately to a good degree of accuracy~~ based on K content alone, whilst external alpha dose rates are predicted less accurately. In combination, total estimated dose rates show good agreement with their counterparts calculated from high-precision methods, with ~~68–98%~~ 95% of our results lying within ~~uncertainties of  $\pm 10\%$  of unity~~ ~~depending on the scenario~~ ~~for scenarios where the alpha dose rate contribution is assumed to be negligible~~. ~~We report better agreement for scenarios where alpha contributions are assumed to be negligible (e.g., in the case of etched, coarse-grained quartz or potassium feldspar)~~

30 ~~Whilst alpha dose rate contributions are predicted the least accurately, scenarios including an alpha component result in at least 80% of predictions lying within uncertainties of  $\pm 10\%$  of unity~~. The use of simplified attenuation factors to correct estimated infinite matrix dose rates does not contribute significantly to resulting scatter, ~~with uncertainties mostly resulting~~

~~from the training equations~~. This study serves as a proof of concept that pXRF measurements, along with a set of linear equations and a simplified correction procedure, can be used to rapidly calculate range-finder environmental dose rates.

## 35 1 Introduction

Trapped charge dating methods such as luminescence and electron-spin resonance dating can be used to determine the time since burial of mineral grains. Age calculation using these methods requires two parameters to be quantified: (1) The equivalent dose ( $D_e$ ), the amount of radiation dose absorbed by the mineral throughout the burial period, measured in Gray (Gy); and (2) The environmental dose rate ( $\dot{D}$ ), the rate at which environmental radiation is emitted by the surrounding sediment matrix and 40 received from cosmic rays, measured in ~~Gy per time unit, e.g.,~~ Gy/a or Gy/ka. Time since burial is thus calculated by:

$$\text{Age} = \frac{D_e}{\dot{D}} \quad (\text{Equation 1})$$

To determine  $\dot{D}$ , various individual dose contributions are calculated and summed:

45

$$\dot{D} = \dot{D}_\alpha + \dot{D}_\beta + \dot{D}_\gamma + \dot{D}_i + \dot{D}_c \quad (\text{Equation 2})$$

Where  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  are the dose rate contributions ~~of from~~ alpha ( $\alpha$ ) and beta ( $\beta$ ) particles and gamma ( $\gamma$ ) ray emissions from the sediment matrix external to the mineral grains being dated, respectively; and  $\dot{D}_c$  is the contribution from cosmic rays 50 bombarding the Earth. The  $\dot{D}_i$  is the sum of contributions from  $\alpha$  and  $\beta$  particles arising from decay processes from sources internal to the mineral grains.

The  $\dot{D}_\alpha$  results from the decay chains of Th and U, and  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  from K, Th and U in the surrounding sediment matrix (Guerin et al., 2011). In most luminescence dating studies, internal  $\alpha$  contributions are assumed to be either negligible (e.g., Duller, 55 1992) or an assumed value is provided (e.g., Mejdahl, 1987; Olley et al., 2004). Internal  $\beta$  contributions are usually calculated using assumed concentrations of the internal K contents (e.g.,  $12.5 \pm 0.5\%$  or  $10 \pm 2\%$ ; Huntley and Baril, 1997; Smedley et al., 2012, respectively) when potassium-rich feldspar (KF) is the mineral being dated. Both the external and internal dose rate contributions are calculated using the infinite matrix (IM) assumption: that within the surrounding sediment, the rate of energy emitted over the range of interest is equal to the rate of absorption (Guerin et al., 2012). During dose rate calculation, individual 60 IM dose rates are adjusted for a range of attenuating factors, including grain size, water content, and the effectiveness of  $\alpha$  particles to ionize mineral crystals (e.g. Durcan et al., 2015 and references therein), ~~all of which influence radiation emission and absorption~~. The  $D_c$  is calculated mathematically from the latitude, longitude, altitude, burial depth and overburden density of samples, using the equations of Prescott and Hutton (1994).

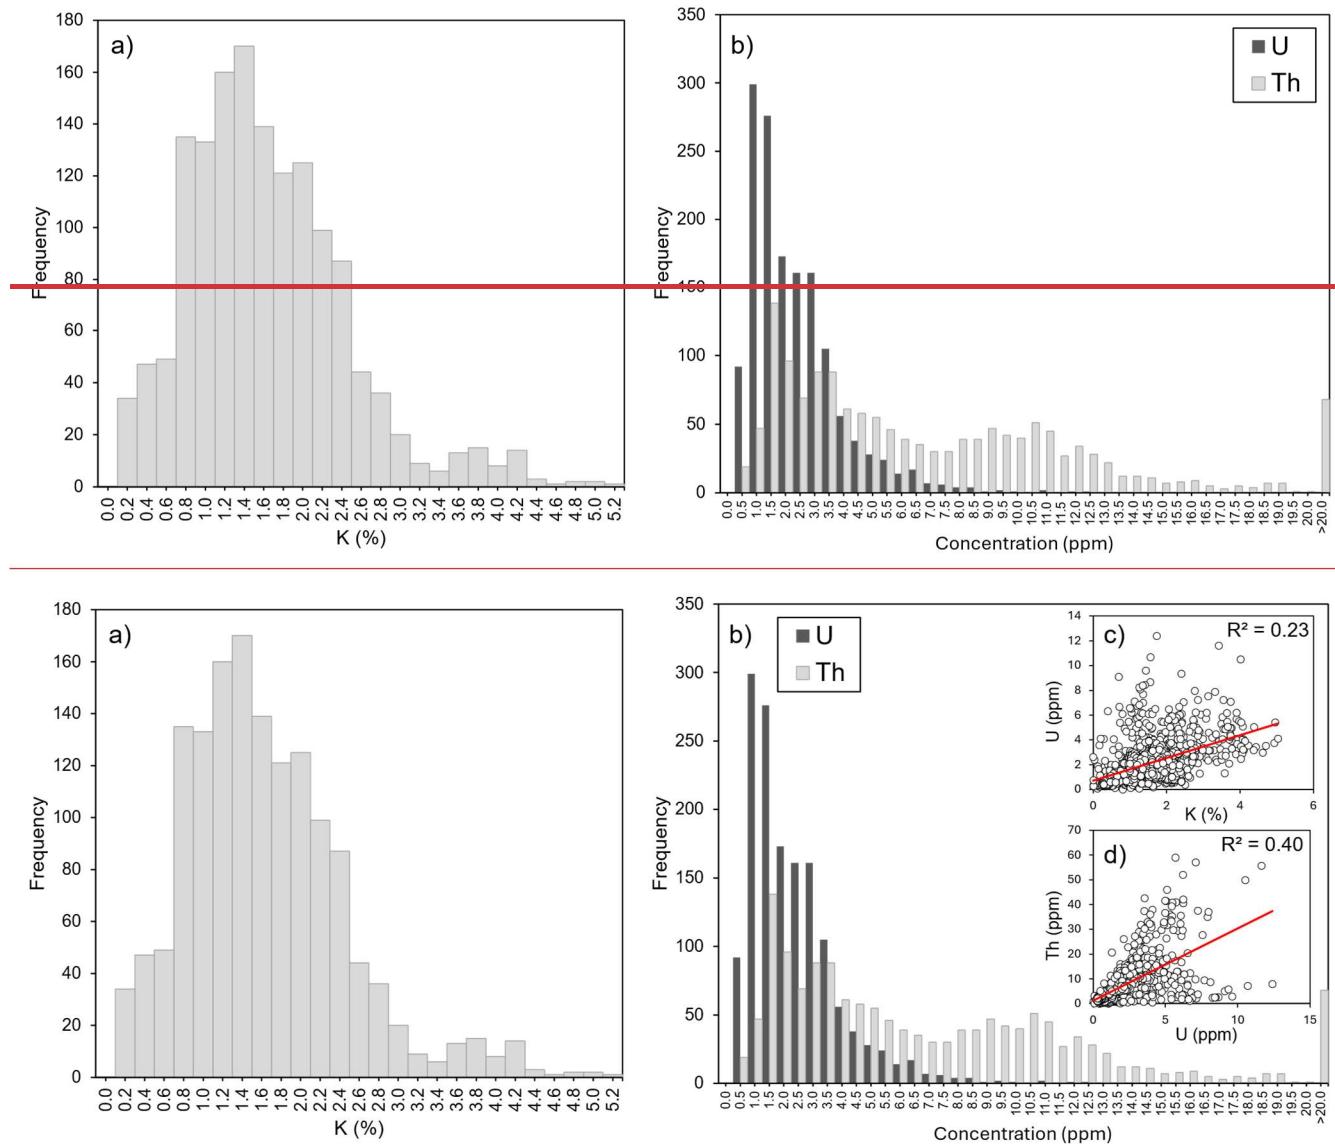

65 Typically, the calculation of  $D_e$  and  $\dot{D}$  require time-consuming and costly laboratory-based sample preparation and measurements. External  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  contributions to  $\dot{D}$  are determined using either geochemical measurements of the K, Th and U concentrations within surrounding sediment, or via direct emission counting. Geochemical measurements are carried out using laboratory methods, such as inductively coupled plasma mass spectrometry (ICP-MS) or neutron activation analysis (NAA, e.g., Woor et al., 2023; Wolfe et al., 2023). Laboratory-based emission counting techniques include thick-source alpha counting (TSAC; e.g., Huntley et al., 1986; Hossain et al., 2002) but emission counting can also be carried out in the field during sample collection using equipment such as portable gamma spectrometers (e.g., Woor et al., 2023). Whilst accurate, these methods typically take hours to weeks, and time or cost restraints can limit sample throughput (e.g., in the case of sending samples to specialist laboratories for high-precision geochemistry).

75 The ability to rapidly and inexpensively assess  $\dot{D}$  is useful in a variety of contexts. Numerous studies have shown that ages can be estimated by rapidly calculating  $D_e$  following truncated sample processing (e.g., skipping the usual mineral separation steps) or by running smaller numbers of sub-sample aliquots than is typical (e.g., Roberts et al., 2009; Durcan et al., 2010). Such ‘range-finder’ dating approaches enable the rapid generation of geochronological data, establishing initial age control that can help refine sampling strategy or identify samples of interest for further laboratory preparation (Roberts et al., 2009; 80 Durcan et al., 2010; Leighton and Bailey, 2015; Alexanderson and Bernhardson, 2016). Moreover, over recent years, the use of portable optically stimulated luminescence (pOSL) readers has increased, offering rapid measurements of photon emission in response to optical stimulation in the field (Sanderson and Murphy, 2010). Signals from pOSL readers have been applied in a variety of geomorphological and archaeological studies (e.g., Bateman et al., 2015; Gray et al., 2018; Stone et al., 2019, 2024; Munyikwa et al., 2021; Rizza et al., 2024) and offer high sample throughput. Environmental dose rates are a key control 85 on pOSL signals (Munyikwa et al., 2021), and therefore being able to rapidly estimate  $\dot{D}_{\text{their}}$  variability between samples and sites, at least in a relative sense, would be a significant advantage for interpreting pOSL data. Rapid and portable  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  determination would also help to assess dose heterogeneity during field sampling, which can arise in complex sedimentary contexts where IM assumptions do not hold, such as where samples are taken close to stratigraphic boundaries or in heterogeneous rock slices (e.g. Nathan et al., 2003; Smedley et al., 2020; Ou et al., 2022).

90

Although range-finder dating studies have shown promising results for the rapid determination of  $D_e$ , less attention has been paid to the rapid measurement of  $\dot{D}$ . Previous work has shown that  $\dot{D}$  can be determined in a matter of hours using laboratory-based emission counting methods (e.g., Ankjægaard and Murray, 2007; Durcan et al., 2010). Ou et al. (2022) also showed that the K concentrations of rock slices used in luminescence dating can be measured accurately with portable X-ray fluorescence (pXRF), and that there is a strong positive correlation between their K contents and their  $\dot{D}_\beta$  (measured independently using thick source  $\beta$  counting). Portable XRF is designed to measure the elemental concentrations of materials in the field (Lemiere, 95 2018), so it could have great potential for rapidly and portably estimating  $\dot{D}$ . However, whilst pXRF can readily determine K

concentrations at magnitudes typical of sediments in luminescence dating studies with an optimized detection limit of 0.005% (Fig.1a; Hall et al., 2014), the normal limits of detection and quantification of U and Th (~3 and 10 ppm, respectively) are typically too high for most sedimentary settings (Fig.1b; Melquiades et al., 2024). [For example, Jankowski and Jacobs \(2018\) used pXRF to measure K, U and Th concentrations in order to assess  \$D\_\beta\$  variability in Australian sediment samples, but U was only detectable in 4-16% of sub-samples.](#)

105 [Figure 1: Histograms of a\) K concentrations and b\) U and Th concentrations from sediments included in the \*\*training\*\*-dataset compiled for this study \(n = 1473; see supplementary information to access the dataset\). Insets c\) and d\) show K concentration vs U concentration and U concentration vs Th concentration, respectively, for the same samples in the dataset.](#)

In this study, we develop a method for rapidly estimating range-finder  $\dot{D}$  by measuring solely the K concentration of sediments using a laboratory-based pXRF. Like the approach of Ou et al. (2022), this method is based on the relationship between K concentrations and  $\dot{D}_\beta$ , which is expanded upon to estimate  $\dot{D}_\alpha$  and  $\dot{D}_\gamma$  using a set of linear regression equations generated from a large, global sediment radionuclide dataset. These training relationships are used to estimate IM  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  contributions based on K concentrations measured using pXRF for samples with known radionuclide contents. Resulting IM dose rates are given simplified mathematical treatments for attenuation and compared with dose rates calculated based on radionuclide concentrations measured using high-precision geochemistry and corrected using typical attenuation procedures. We demonstrate that it is possible to rapidly estimate  $\dot{D}$  with reasonable accuracy and precision by using pXRF-derived K concentrations only, a set of simple linear regression equations, and a streamlined attenuation approach.

## 2 Methods

### 2.1 2.1 Scaling relationshipsCorrelations between K concentration and dose rate components

To estimate  $\dot{D}$  based on the K concentration alone, we first establish and test three scaling relationshipsrelationships: 1)  $\dot{D}_\beta$  is correlated with K concentration, 2)  $\dot{D}_\gamma$  is correlated with  $\dot{D}_\beta$ , and 3)  $\dot{D}_\alpha$  is correlated with  $\dot{D}_\gamma$ .  
 $\dot{D}_\beta \propto K$  (Equation 3)

$\dot{D}_\gamma \propto \dot{D}_\beta$  (Equation 4)

$\dot{D}_\alpha \propto \dot{D}_\gamma$  (Equation 5)

Equation 3 is the Various previous studies have demonstrated a positive correlation between IM  $\dot{D}_\beta$  and the K concentration of sediment, as has been previously demonstrated (Ankjægaard and Murray, 2007; Roberts et al., 2009; Ou et al., 2022). Equation 4 is the positive correlation between IM  $\dot{D}_\gamma$  and IM  $\dot{D}_\beta$ . Similarly, Ankjægaard and Murray (2007) showed that IM  $\dot{D}_\gamma$  can be estimated from IM  $\dot{D}_\beta$  using either a second-order polynomialpolynomial regression relationship or a ratio of  $\sim 0.50$  (determined from the slope of a linear fit), from a large suite of luminescence dating samples and emission-counting methods ( $n = 3758$ ). Roberts et al. (2009) produced very similar results using linear regression, with a ratio of 0.59 ( $n = 427$ ). Lastly, we hypothesize that IM  $\dot{D}_\alpha$  scales should be correlated with IM  $\dot{D}_\gamma$  (Equation 5) because  $\alpha$  particles are contributed from the U and Th decay chains (not K), and IM  $\dot{D}_\gamma$  scales strongly with U and Th concentration (supplementary Fig. S1g, h; Guerin et al., 2011). Therefore, the greater the U and Th concentration, the greater the IM  $\dot{D}_\gamma$  and, by extension, the IM  $\dot{D}_\alpha$ . Using these scaling relationships/principles 2, we hypothesize that it is possible to estimate IM  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$ , and therefore  $\dot{D}$ , from an initial input of the K concentration.

#### 2.1.1 Training Radionuclide dataset

To establish regression relationships and parameterise Equations 3–5between K concentration and IM  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$ , we built compiled a global training dataset of K, U and Th concentrations from published luminescence dating studies, projects

undertaken at the University of the Fraser Valley's Luminescence Dating Laboratory, [Canada](#), and previous compilations of  
140  $\bar{D}$  data (Fig. 2; Durcan et al., 2015; Woor et al., 2022; Walsh et al., 2023). The resulting dataset comprises 1473 samples from  
geographic locations around the world with a broad range of K, U and Th concentrations (Fig.1, Table 1; see supplementary  
information for the full dataset, including information for calculating  $\bar{D}_c$ ). Infinite-matrix  $\bar{D}_\alpha$ ,  $\bar{D}_\beta$  and  $\bar{D}_\gamma$  were calculated from  
these radionuclide data in the Dose Rate and Age Calculator (DRAC; Durcan et al., 2015), using the conversion factors of  
Guerin et al. (2011). [Linear regression was](#) [Regression models were](#) used to parameterise [Equations 3–5](#). [the relationships](#)  
145 [outlined in Section 2.1](#). We also provide regression models based on the conversion factors of Cresswell et al. (2018) in Fig.  
S2. However, whilst the equations of these regressions differ slightly, their predictive ability, relative to dose rates calculated  
from high precision methods, is the same as long as the same conversion factors used for the rapid predictions and high  
precision calculations are the same.

150 **Table 1: Descriptive statistics of the radionuclide concentrations included within the [training](#) dataset. Concentrations are given in**  
% for K and ppm for U and Th (n = 1473). The geographical distributions of samples can be seen in [Figure](#) [Fig. 2](#) and frequency  
distributions of radionuclide concentrations in [Figure](#) [Fig. 1](#).

Radionuclide	Mean	Standard deviation	Min.	Max.
K (%)	1.52	0.82	0.004	5.03
U (ppm)	2.09	1.56	0.020	12.40
Th (ppm)	7.17	7.18	0.030	59.00

155

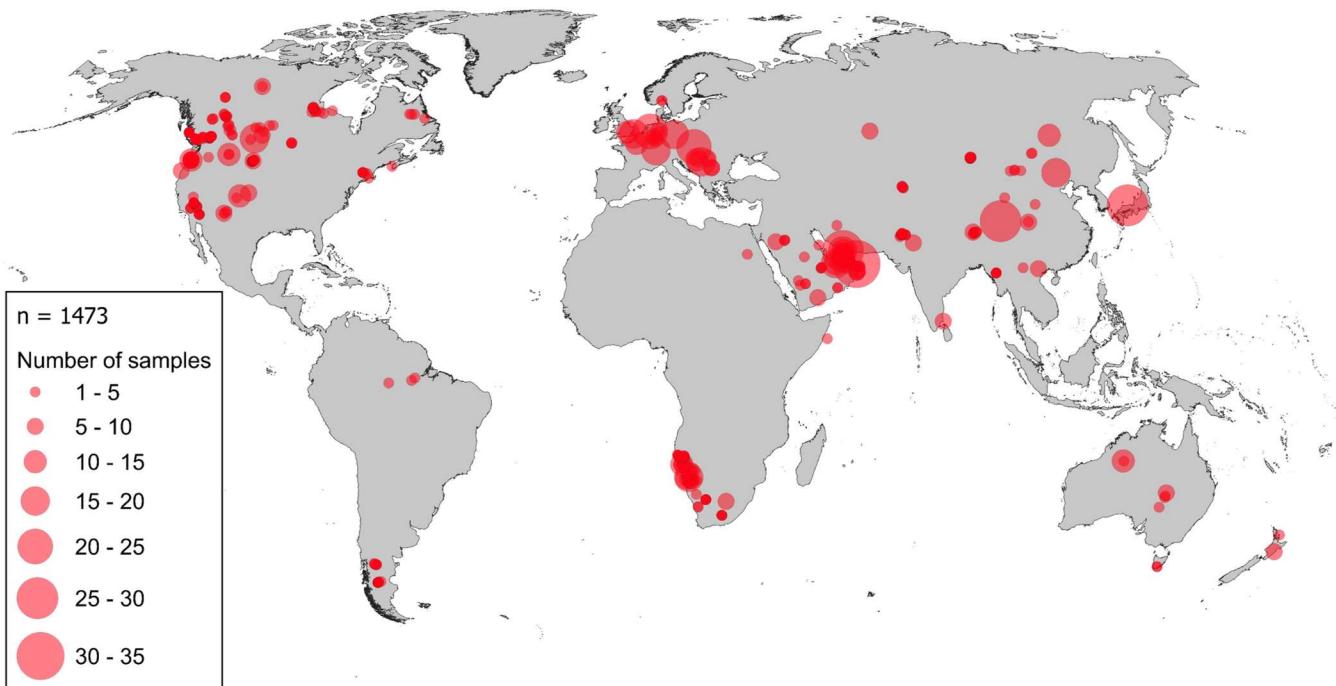

Figure 2: Map of the sedimentary radionuclide samples compiled within the [training](#)-dataset used in this study.

160 **2.2 pXRF measurements of K concentrations**

Portable XRF was used to measure the K concentrations of 67 sediment dosimetry samples available from the University of the Fraser Valley's Luminescence Dating Laboratory, for which K, U and Th concentrations have previously been measured with NAA or ICP-MS (sample locations and radionuclide concentrations are provided in the supplementary material). Sediments were oven dried and finely milled prior to packing into cups for analysis. Measurements were carried out using a

165 bench-mounted Olympus Vanta pXRF (Fig.3), with each measurement taking ~90 s. The pXRF system was operated in [the](#) [two](#)-beam '[geochem](#)' mode, [meaning that samples were measured using two X-ray beams at 40 and 10 kV \(Andrew and Barker, 2018\)](#). [Each](#) sample was measured three times with the beams hitting different areas of the sediment surface. Throughout the measurements, five certified reference materials ([CRMs](#)) with known elemental concentrations and an analytical blank were measured five times each to ensure there was no contamination in the system. The system was cleaned

170 with an air duster between each measurement.

[The results of pXRF analysis were corrected using a linear calibration equation, following previous studies \(e.g., Hall et al., 2014; Andrew and Barker, 2018\). This calibration equation was the linear relationship between the pXRF-measured K concentrations of the five CRMs and their known K concentrations \(Fig. S5\). The limit of detection \(LOD\) and limit of quantification \(LOQ\) for our instrument, with respect to K concentration, were determined as three times the standard deviation and ten times the standard deviation of repeat measurements of the CRM with the lowest K concentration, respectively \(Le](#)

Vaillant et al., 2014; Andrew and Barker, 2018; Table S1). The LOD for K in our instrument is 0.015% and the LOQ is 0.049%. Further details of further information about instrument calibration and LOD and LOQ determination, the reader is referred to are provided in the Supplementary Information.

180

Resulting pXRF K concentrations were expressed as a percentage, corrected using the calibration and averaged ( $n = 3$ ) for each of the 67 samples. Uncertainties associated with K concentrations were calculated using the standard deviation of the repeat measurements, as well as the standard error associated with the calibration. The measurements were then compared with K concentrations determined using high-precision geochemistry (ICP-MS or NAA) to assess the accuracy of pXRF 185 measurements.

190

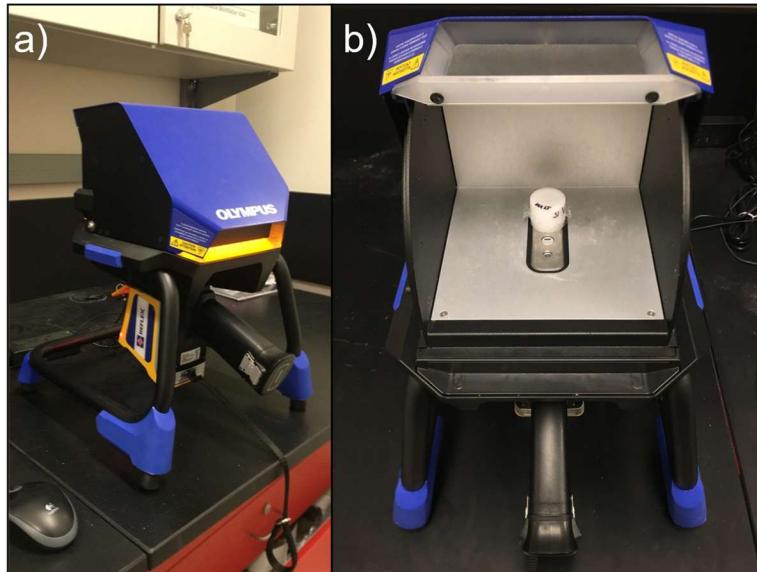

Figure 3: a) The pXRF in its bench mount with the X-ray shield closed during sample measurement. b) A sample loaded into a cup for analysis placed inside the pXRF's measurement chamber. For scale, the sample is ~2.5 cm in diameter.

## 2.3 Dose rate calculations

### 2.3.1 High-precision dose rates

195 To test the accuracy of the rapid, pXRF approach to estimating IM dose rates, total  $\dot{D}$  was calculated for the same 67 sediment samples using their high-precision radionuclide contents. Total  $\dot{D}$  was calculated for five common, theoretical luminescence dating targets: (1) 180-250  $\mu\text{m}$  quartz (that hasd undergone etching, the removal of the  $\alpha$ -irradiated outer portion of the grain

with hydrofluoric acid); (2) 180-250  $\mu\text{m}$  KF (etched); (3) 180-250  $\mu\text{m}$  KF (not etched); (4) 4-11  $\mu\text{m}$  quartz; and (5) 4-11  $\mu\text{m}$  polymineral grains.

200

The radionuclide conversion factors used to transform radionuclide concentrations into IM dose rates, the attenuation factors used to correct the IM dose rates (grain size, etch depth, grain size,  $\alpha$  and  $\beta$  attenuation,  $\alpha$  efficiency and water content), the assumptions relating to  $\dot{D}_i$  (where applicable), and the parameters used to calculate  $\dot{D}_c$  using the equations of Prescott and Hutton (1994) are summarized in Table 2 for each of these theoretical targets. An arbitrary, theoretical water content of  $5 \pm 2\%$  was used to correct dry dose rates using the method of Zimmerman (1971). The contribution of internal  $\alpha$  particles was assumed to be negligible in all cases. All dose rate calculations were carried out using DRAC and uncertainties propagated in quadrature (Durcan et al., 2015). All data are available in the supplementary information.

210

Table 2: Summary of the parameters and assumptions used to calculate high precision  $\dot{D}$  for a suite of theoretical luminescence dating targets. Calculations were carried out using DRAC (Durcan et al., 2015).

Dose contribution	Input parameter	180-250 $\mu\text{m}$ quartz	180-250 $\mu\text{m}$ K-feldspar (etched)	180-250 $\mu\text{m}$ K-feldspar (not etched)	4-11 $\mu\text{m}$ polymineral	4-11 $\mu\text{m}$ quartz					
External and internal dose rates	IM $\dot{D}_\alpha$ , $\dot{D}_\beta$ and $\dot{D}_\gamma$ (Gy/ka)	Calculated from known radionuclide contents using the conversion factors of Guerin et al. (2011)									
	Internal K (%)	NA	12.5 $\pm$ 0.5 (Huntley and Baril, 1997)		NA						
	Min. grain size ( $\mu\text{m}$ )	180		4							
	Max. grain size ( $\mu\text{m}$ )	250		11							
	Alpha grain size attenuation	Brennan et al. (1991)									
	Beta grain size attenuation	Guerin et al. (2012): values for quartz and feldspar, respectively									
	Min. etch depth ( $\mu\text{m}$ )	8	NA		NA						
	Max. etch depth ( $\mu\text{m}$ )	10	NA		NA						
	Beta etch depth attenuation	Bell (1979)									
	$\alpha$ -value	NA	0.15 $\pm$ 0.05 <sup>a</sup>	0.086 $\pm$ 0.004 <sup>b</sup>	0.03 $\pm$ 0.003 <sup>c</sup>						

	Water content (%)	5±2
Cosmic ray dose rate	Latitude (decimal degrees)	As measured during sampling
	Longitude (decimal degrees)	As measured during sampling
	Altitude (m asl)	As measured during sampling
	Depth (m)	As measured during sampling (±0.05)
	Overburden density (g/cm <sup>3</sup> )	1.8±0.1

<sup>a</sup> Value from Balescu and Lamothe (1994).

<sup>b</sup> Value from Rees-Jones (1995).

215 <sup>c</sup> Value from Mauz et al. (2006).

### 2.3.2 Rapid dose rates

The statistical relationships derived from the [radionuclide training](#) dataset were used to convert pXRF K measurements into IM  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$ , [following using Equations 3–5](#) [the equations given in Fig. 4](#). These IM dose rates were also corrected for a [theoretical](#) water content of 5 ± 2% (Table 2) using the equations of Zimmerman (1971)). [The choice of water content here](#)

220 [is purely arbitrary for the purpose of comparison with the high-precision dose rates. In practice, it should be users should apply](#) [determined and based on prior knowledge of the environment, or either in field or laboratory testing their own water content](#) [estimate for rapid  \$\dot{D}\$  estimation using this approach](#). To rapidly generate total  $\dot{D}$  estimates, we [took followed](#) the approach of

225 Aitken (1985) whereby water-corrected dose rates are further corrected by multiplication with simplified attenuation factors ([Table 3](#)). This approach is in lieu of the more detailed set of attenuation parameters and calculation steps outlined in Table 2,

230 which are carried out by software packages like DRAC (Durcan et al., 2015). Aitken (1985) suggests that the water-corrected  $\dot{D}_\beta$  of coarse mineral grains that have been etched should be corrected by a factor of 0.9. For the variety of different grain sizes of the theoretical targets in this study, and  $\dot{D}_\alpha$ , which is a contributor to the total  $\dot{D}$  for luminescence dating targets that have not undergone etching, similar mean attenuation factors are provided in Table 3. These mean attenuation factors were calculated using the grain size attenuation data of Brennan et al. (1991). Attenuated  $\dot{D}_\alpha$  values were then corrected further for

235  $\alpha$  efficiency using the  $\alpha$ -values given in Table 2. Internal  $\beta$  dose rates were accounted for in the case of KF or polymineral targets by treating them as constant values for given grain sizes, etch depths and an internal K concentration of 12.5 ± 0.5% (Huntley and Baril, 1997), as calculated by DRAC using the absorption factors of Guerin et al. (2012) (Table 3). Internal  $\alpha$  particle contributions are assumed to be negligible in all cases. The  $\dot{D}_c$  was calculated using the equations of Prescott and Hutton (1994) with the same input data as described in Table 2.

**Table 3: Summary of the parameters and assumptions used to calculate rapid dose rates using the IM dose rates predicted based on pXRF K concentrations and training data relationships.** Water contents,  $\alpha$ -values and  $\dot{D}_c$  calculation parameters are the same as Table 2.

Input parameter	180-250 $\mu\text{m}$ quartz	180-250 $\mu\text{m}$ K-feldspar (etched)	180-250 $\mu\text{m}$ K-feldspar (not etched)	4-11 $\mu\text{m}$ polymineral	4-11 $\mu\text{m}$ quartz
IM $\dot{D}_\alpha$ , $\dot{D}_\beta$ and $\dot{D}_\gamma$ (Gy/ka)	Estimated based on an initial pXRF K measurement using the relationships derived from the training data regression relationships (Equations 3-5)				
$\dot{D}_\alpha$ attenuation <sup>a</sup>	NA		0.1 $\pm$ 0.01	0.9 $\pm$ 0.02	
$\dot{D}_\beta$ attenuation <sup>b</sup>	0.9 $\pm$ 0.01			NA <sup>b</sup>	
Internal $\dot{D}_\beta$ (Gy/ka) <sup>c</sup>	NA	0.773 $\pm$ 0.138		0.026 $\pm$ 0.012	NA

<sup>a</sup> Mean attenuation factors were calculated using the data of Brennan et al. (1991).

<sup>b</sup> Mean attenuation factors were calculated using the data of Guerin et al. (2012). A mean  $\dot{D}_\beta$  attenuation factor of  $0.99 \pm 0.003$  was calculated for the 4-11  $\mu\text{m}$  range, so no correction was applied.

<sup>c</sup> Calculated using DRAC for the grain sizes, etch depths and an internal K concentration given in Table 2.

### 3 Results

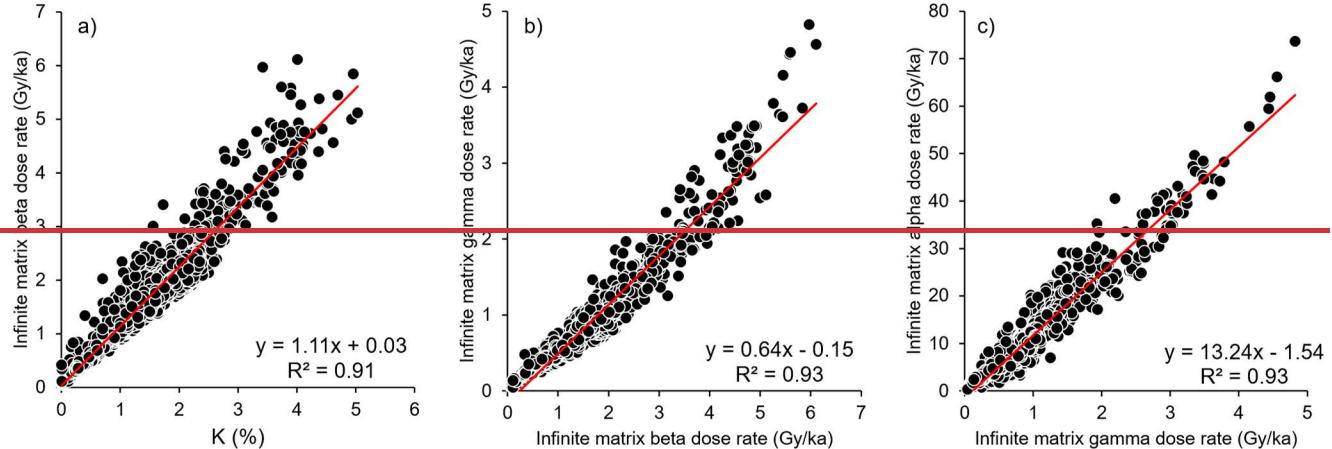

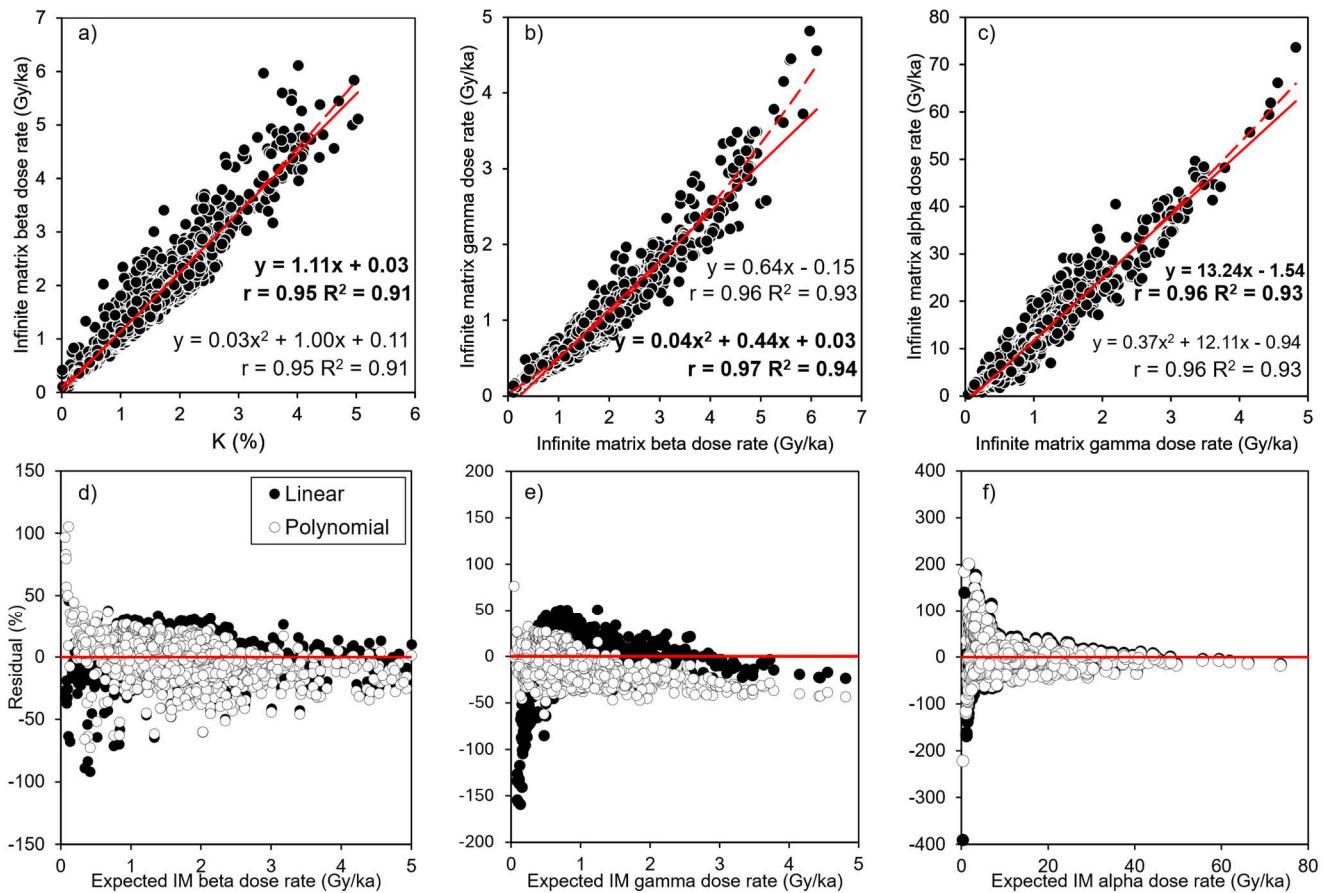

#### 3.1 Training Radionuclide dataset and regression relationships

Figure 4 (a-c) shows the results of IM  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  calculated from the K, U and Th values comprising the 1473 sample training radionuclide dataset and the conversion factors of Guerin et al. (2011). See Fig. S2 in the supplementary material for the same equations calculated using the conversion factors of Cresswell et al. (2018), the results of which are very similar to those shown in Figure 4. The residuals of the results of these relationships are also shown (Fig. 4d-f), which areas the difference between dose rates predicted using the different regression models shown in Figure 4a-c with inputs from the high-precision dataset, and the high-precision expected values (the results are shown in Fig. S2). Linear regressions fitted between the variables of Equations 3-5 are representative, with  $R^2$  values exceeding 0.90 in all cases (Fig. 4), and all models have p-values  $<0.05$ , indicating the significance of these relationships at the 95% confidence level. As expected from Equations 3-5, we find very strong positive scaling relationships between K concentration and IM  $\dot{D}_\beta$  (Fig. 4a), IM  $\dot{D}_\beta$  and IM  $\dot{D}_\gamma$  (Fig. 4b) and IM  $\dot{D}_\gamma$  and IM  $\dot{D}_\alpha$  (Fig. 4c), with Pearson's correlation coefficient ( $r$ )  $>0.95$  in all cases. For ease of interpretation, uncertainties are not shown in Fig. 4 as they are small relative to the dose rate values, with  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  values having mean relative uncertainties of 6.8%, 5.1% and 5.0%, respectively. These uncertainties are a product of the uncertainties of the K, U and Th concentrations used to calculate them, and the uncertainties associated with the radionuclide conversion factors of Guerin et al. (2011).

The regression models fitted between the variables are representative, with  $R^2$  values exceeding 0.90 in all cases (Fig. 4), and all models have p-values  $<0.05$ , indicating the significance of these relationships at the 95% confidence level. For all

relationships, linear fits were compared with second order polynomials. In the case of the relationships between K concentration vs. IM  $\dot{D}_\beta$  (Fig. 4a) and IM  $\dot{D}_\gamma$  vs. IM  $\dot{D}_\alpha$  (Fig. 4c), we prefer the simpler linear models due to the  $R^2$  values being the same as using the polynomials, and their residuals producing very similar plots (Figs. 4d, f; Figs. S2a, c). A second order polynomial fit was used to describe the relationship between IM  $\dot{D}_\beta$  and IM  $\dot{D}_\gamma$  as it resulted in a higher  $R^2$  value relative to the linear fit ( $R^2 = 0.94$  and  $0.93$ , respectively). The residuals of the second order polynomial relationships for IM  $\dot{D}_\beta$  vs. IM  $\dot{D}_\gamma$  are also more tightly clustered around 0, avoiding the tail of underestimations for low values that is observed for the linear model (Fig. 4e). These underestimates of IM  $\dot{D}_\gamma$  are occur because the linear model has a negative intercept, which can result in negative IM  $\dot{D}_\gamma$  estimates in scenarios where IM  $\dot{D}_\beta$  is  $<0.23$  Gy/ka. However, it is notable that for higher dose rates ( $>1$  Gy/ka), the polynomial fit results in greater underestimations than the linear fit (Fig. 4b). So, for samples with low expected gamma dose rates ( $<1$  Gy/ka), it is advisable to use the polynomial fit. for samples sitting at the very smallest or largest dose rates.

The root mean squared errors (RMSEs) of each relationship were calculated by comparing the predicted variable in each case with the observed variable determined with high-precision chemistry (Fig. S2). For the chosen models, the RMSEs for the predicted IM  $\dot{D}_\beta$ , IM  $\dot{D}_\gamma$ , and IM  $\dot{D}_\alpha$  values are 0.29, 0.30 and 2.40 Gy/ka, respectively. The linear regression equations shown in Fig. 4 form the basis for subsequent rapid dose rate estimation using an initial input of K concentration measured with pXRF, with their RMSEs providing uncertainties that are propagated into the final uncertainties on predicted dose rates.

**Figure 4: Training data** [Regression](#) relationships for: a) K concentration and IM  $\dot{D}_\beta$ , b) IM  $\dot{D}_\beta$  and IM  $\dot{D}_\gamma$ , and c) IM  $\dot{D}_\gamma$  and IM  $\dot{D}_\alpha$ . Equations in bold denote the model fits selected for dose rate predictions in this study. Solid red lines denote the linear trendlines and dashed red lines denote the second order polynomial trendlines (n=1473). Pearson's correlation coefficient (r) and  $R^2$  values are given for each relationship. The standard errors for the slopes and intercepts of the regression equations and root mean squared errors (RMSEs) of the linear relationships are a)  $\pm 0.290.01$  and  $\pm 0.02$ , b)  $\pm 0.005$  and  $\pm 0.010.17$ , and c)  $\pm 2.40$  Gy/ka  $\pm 0.1$ .

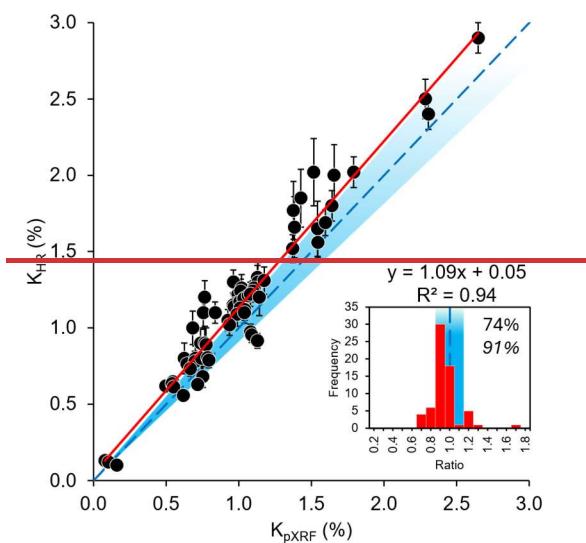

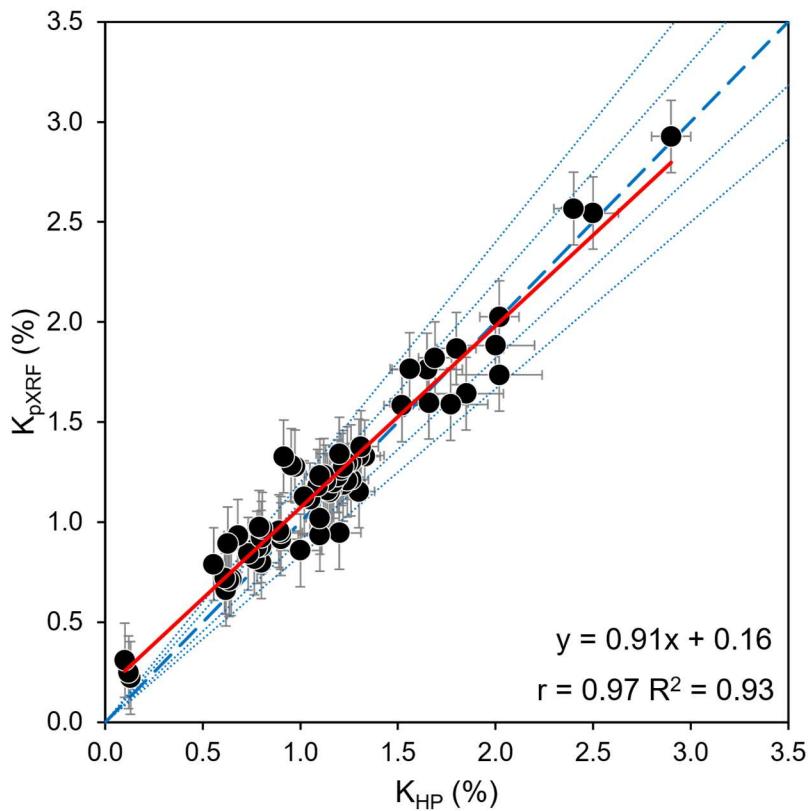

285 and  $\pm 0.4$ . The RMSEs of the polynomial relationships are a) 0.32, b) 0.30 and c) 2.45 Gy/ka. Panels d-f show the residuals of the relationships in a-c, expressed as a percentage of the expected dose rate, in each case plotted against the expected dose rate calculated with high-precision methods.

### 3.2 Portable XRF K concentrations

The results of the training dataset presented in Section 3.1 (Fig. 4) provide linear regression relationships that show that  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  can be estimated from an initial input of the K concentration. Of the 67 samples analysed using pXRF, 66 gave results above the detection limit LOD of the instrument (LOD = 0.015%). The only sample that failed to yield a detectable result had a K concentration of  $0.02 \pm 0.01\%$  as measured with NAA. Whilst this low value determined by NAA is in fact higher than the LOD, it also falls beneath the LOQ (LOQ = 0.049%), which may explain why it was not detectable if it was not accurately quantifiable. All of the 66 samples above the LOD were also above the LOQ. Based on the training dataset of natural sediment radionuclide contents compiled in this study, sediments with such low K concentrations are rare in nature (Fig. 1; Table 1). Of the 1473 samples included in the training dataset, only 14 have K concentrations  $<0.1\%$ , which represents just 1% of the dataset. Portable XRF should, therefore, be able to provide estimates of K contents in the majority of sedimentary contexts if the LOD and LOQ values are similar to those calculated here.

Potassium concentrations determined with pXRF show a strong, positive correlation with K concentrations measured using high-precision methods ( $R^2 = 0.9497$ ), with central values agreeing closely between the two datasets ( $R^2 = 0.93$ ; Fig. 5); Fig. 5. The pXRF data are calculated using the mean of three measurements with very small standard deviations relative to mean concentrations (0.0004–0.017%), which demonstrates the consistency of the repeat measurements. Of the 66 samples that yielded detectable results, 74.65% have mean pXRF K contents with central values within  $\pm 10\%$  of unity with their high-precision counterparts and 94.83% are within  $\pm 20\%$ . However, if uncertainties are considered, then all pXRF K concentrations lie within 20% of unity with high-precision values. The lowest K concentration measured using pXRF was  $0.0822 \pm 0.00118\%$ , closely corresponding with a high-precision concentration of  $0.13 \pm 0.01\%$  measured with ICP-MS. The highest K concentration measured using pXRF was  $2.6593 \pm 0.0118\%$ , again closely corresponding with a high-precision concentration of  $2.90 \pm 0.10\%$  measured using NAA. The regression equation,  $y = 0.91x + 0.16$ , slope of the regression equation,  $1.09 \pm 0.03$ , shows that the calibrated pXRF instrument measurements tend to generally slightly underestimate overestimate the low high-precision K concentrations ( $<1.5\%$ ) whilst slightly underestimating higher K concentrations ( $>1.5\%$ ); Fig. 5).

Similarly accurate and reliable results were also obtained for the certified reference materials used for calibrating measurements (Table S1). Blank samples yielded K concentrations consistently below detection limits, indicating that no contamination was present in the pXRF system throughout the measurements.

**Figure 5:** Potassium (K) concentrations measured using pXRF ( $K_{\text{pXRF}}$ ) compared with K concentrations derived from high-precision geochemistry methods ( $K_{\text{HP}}$ ). The red line denotes the unweighted linear trendline ( $n = 66$ ). Pearson's correlation coefficient ( $r$ ), calculated relative to the regression line, and  $R^2$  values, calculated relative to the unity line, are shown for each dataset. The standard error of the slope and intercept of the regression equation are  $\pm 0.03$  and  $\pm 0.04$ , respectively. The thick dashed blue line represents

~~unity and blue shaded area represent unity the thinner blue lines represent  $\pm 10\%$  and  $\pm 20\%$ . The inset plot shows frequency distributions of the ratios between  $K_{pXRF}$  and  $K_{HP}$ , with the blue shaded area representing  $\pm 10\%$  unity. Percentages show the proportion of central values that fall within this range and values in italics show the proportion of values that fall within  $\pm 20\%$  of unity.~~

### 325 3.3 Comparison between rapid and high precision IM and total dose rates

Figure 6 shows the results of calculating IM  $\dot{D}_\alpha$ ,  $\dot{D}_\beta$  and  $\dot{D}_\gamma$  using rapid pXRF K measurements ~~and using~~ the regression relationships derived from the ~~training radionuclide~~ dataset (Fig. 4), in comparison to calculations based on high-precision radionuclide measurements and the conversion factors of Guerin et al. (2011). The uncertainties associated with the rapid dose rate values are similar between samples for each emission type. This is because uncertainties ~~are incorporate the calculated using the margin of error of prediction RMSE of the predictive models (Fig. 4), which are the same for each sample, as well as smaller uncertainties contributed by the input K concentrations measured using the pXRF (Fig. 5). The results of calculating IM dose rates using the equations derived from the conversion factors of Cresswell et al. (2018) are shown in comparison to the results of Figure 4 in Figure S3 of the supplementary material. The results of both approaches are within uncertainties of each other and produce  $R^2$  values of  $>0.99$ , signifying that both methods produce virtually indistinguishable results. the greatest contribution to which are the standard errors associated with the training dataset regressions (Table S2). Due to this, the mean uncertainties associated with each dataset give a representative sense of the magnitude of uncertainty for each IM dose rate (the standard deviation of these mean uncertainties is  $<0.001$  Gy/ka in all cases). The mean uncertainty for rapid IM  $\dot{D}_\alpha$  predictions is the highest ( $\pm 3.95$  Gy/ka), relative to a mean rapid IM  $\dot{D}_\alpha$  of  $6.38 \pm 4.35$  Gy/ka (reported uncertainties around mean values are 1 $\sigma$ ). For IM  $\dot{D}_\beta$  mean uncertainty is  $\pm 0.48$  Gy/ka, relative to a mean rapid IM  $\dot{D}_\beta$  of  $1.17 \pm 0.51$  Gy/ka. Finally, for IM  $\dot{D}_\gamma$ , mean uncertainty is  $\pm 0.28$  Gy/ka, relative to a mean rapid IM  $\dot{D}_\gamma$  of  $0.60 \pm 0.33$  Gy/ka.~~

~~Significant, positive Pearson's correlation coefficients ( $r$ ) are reported correlations between rapid and for the trendlines of the high-high-precision dose rates vs. the rapid estimates are reported for all external dose contributions and, in all cases, show that the predictions increase with the expected values (Figure 6a-c). Rapid estimates of IM  $\dot{D}_\beta$  based on pXRF K measurements show the ~~elosest~~ strongest positive correlation agreement with their high-precision counterparts, yielding an  $R^2$  value of 0.92 ( $r = 0.96$ ) and the ~~best~~ closest agreement relative to the unity line ( $R^2 = 0.75$ ; Fig. 6b). Calculating ratios between rapid and high-precision values shows that 7495% of central values of rapid IM  $\dot{D}_\beta$  results are within uncertainties of  $\pm 10\%$  of unity and 94100% are within uncertainties of  $\pm 20\%$ . When uncertainty ranges are considered, all values fall within  $\pm 10\%$  of unity. The regression line shows that there is a tendency for the model to consistently overestimate IM  $\dot{D}_\beta$  by  $\sim 10\%$  and the regression line follows a very similar trajectory to the 1:1 line (Fig. 6b). The predicted IM  $\dot{D}_\gamma$  values, calculated from the predicted IM  $\dot{D}_\beta$  results, have a weaker, yet still ~~strong~~ good, linear positive relationship with high-precision IM  $\dot{D}_\gamma$  ( $R^2 = 0.57$ ;  $r = 0.76$ ; Fig. 6c). The slope of the linear trendline for the rapid IM  $\dot{D}_\gamma$  vs. high precision IM  $\dot{D}_\gamma$  is lower than that of IM  $\dot{D}_\beta$ , showing that the rapid method generally overestimates IM  $\dot{D}_\gamma$  more than IM  $\dot{D}_\beta$  for values  $<0.75$  Gy/ka. Despite this, a similar proportion and a smaller proportion of central values fall within uncertainties of  $\pm 10\%$  (46%) and  $\pm 20\%$  (62%) and  $\pm 20\%$  of~~

355 unity (98%), relative to the predicted IM  $\dot{D}_\beta$  ( $R^2 = 0.54$ ). However, when uncertainty ranges are considered, the majority of predicted IM  $\dot{D}_\gamma$  values overlap with the  $\pm 10\%$  of unity range. The predicted IM  $\dot{D}_\alpha$  values show the weakest positive relationship correlation with the high precision values ( $R^2 = 0.3814$ ; Fig. 6a), with the fewest central values falling within  $\pm 10\%$  of unity (21.65%) and  $\pm 20\%$  (35.71%) of unity, relative to the other predicted IM external dose rates. The IM  $\dot{D}_\alpha$  trendline also has the lowest slope (0.3133), showing that, generally, the training-regression relationship overestimates IM  $\dot{D}_\alpha$  values  $<7.5$  Gy/ka, but will underestimate those  $>7.5$  Gy/ka, relative to results calculated using high-precision geochemistry (Fig. 6a). A negative  $R^2$  value, relative to the unity line, of -0.11 indicates the poor fit of the regression model between IM  $\dot{D}_\alpha$  predictions and their high-precision counterparts.

360 For both the predicted IM  $\dot{D}_\alpha$  and IM  $\dot{D}_\gamma$  values, the use of a linear regression relationships with a negative intercepts (Fig. 4b, 4c) can result in negative outputs due to low input values (Fig. 6a, e). For the samples analyzed with pXRF in this study, negative IM  $\dot{D}_\alpha$  and  $\dot{D}_\gamma$  values are predicted for three samples that have K concentrations  $<0.16\%$ , corresponding with predicted IM  $\dot{D}_\beta$  values of  $<0.21$  Gy/ka. Using the regression relationship given in Fig. 4b, negative IM  $\dot{D}_\gamma$  results will occur when input IM  $\dot{D}_\beta$  is  $<0.23$  Gy/ka, which, using the regression relationship of Fig. 4a, occurs for input K concentrations  $<0.18\%$ . Using the regression relationship given in Fig. 4e, negative IM  $\dot{D}_\alpha$  will result when input IM  $\dot{D}_\gamma$  is  $<0.1242$  Gy/ka, which corresponds to an initial K concentration of  $<0.3515\%$ . However, we report no negative IM  $\dot{D}_\alpha$  results due to all pXRF K measurements that were above the LOD in this study being greater than exceeding the threshold of 0.15%.

375 Whilst IM  $\dot{D}_\beta$  is generally predicted accurately (within  $\pm 24\%$  of unity) by the rapid method, overestimations by up to  $\sim 300\%$  are apparent for a few samples with low radionuclide concentrations (Figs. 6d-f). The IM  $\dot{D}_\gamma$  is also overestimated at low radionuclide concentrations, by up to  $\sim 400\%$  (Fig. 6d-f). The IM  $\dot{D}_\alpha$  and IM  $\dot{D}_\gamma$  are overestimated with increasing K contents in sediments, as measured by high-precision methods (Fig. 6d). For IM  $\dot{D}_\alpha$ , this overestimation is as much as  $\sim 5600\%$  at  $\sim 2.55\%$  K, whereas overestimation is lower for IM  $\dot{D}_\gamma$ , at only around  $\sim 200\%$  for similar K concentrations (Fig. 6d), and . This discrepancy overestimation of IM  $\dot{D}_\alpha$  is explained by the fact that the rapid pXRF approach is solely based on K concentration. Overestimations in IM  $\dot{D}_\alpha$  and IM  $\dot{D}_\gamma$  are also apparent when sediment U and Th contents are low ( $<1.5$  and  $<5$  ppm, respectively), relative to the mean U and Th contents of sediments in the training-radionuclide dataset (Fig. 6e, f; Table 1), as measured by high precision methods. The IM  $\dot{D}_\gamma$  is contributed by the decay chains of K, U and Th and there is a reasonably strong correlation between K concentration and IM  $\dot{D}_\gamma$  in the training-global radionuclide dataset ( $R^2 = 0.72$ , Fig. S1f). By contrast, IM  $\dot{D}_\alpha$  only arises due to U and Th decay, explaining why IM  $\dot{D}_\gamma$  is predicted with greater accuracy than IM  $\dot{D}_\alpha$  by the rapid method based solely on K concentration.

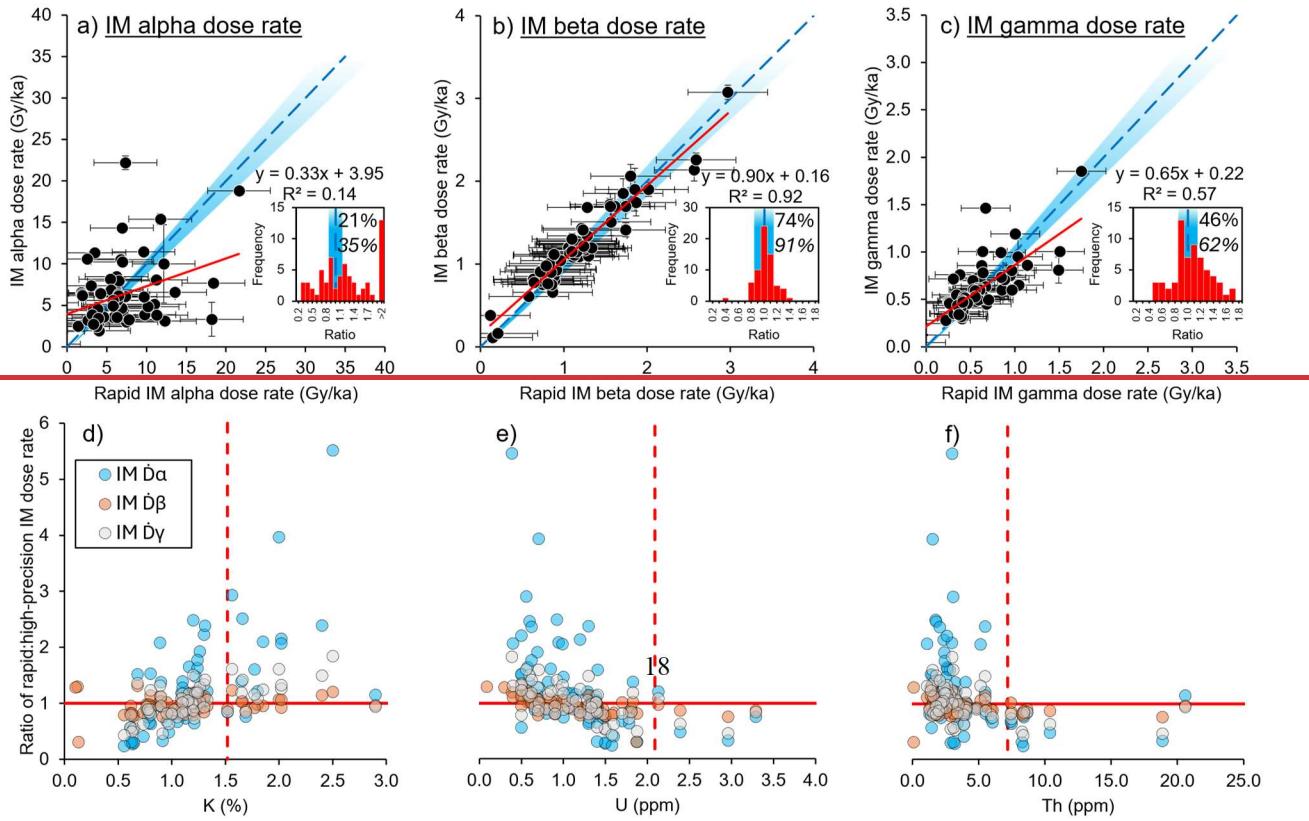

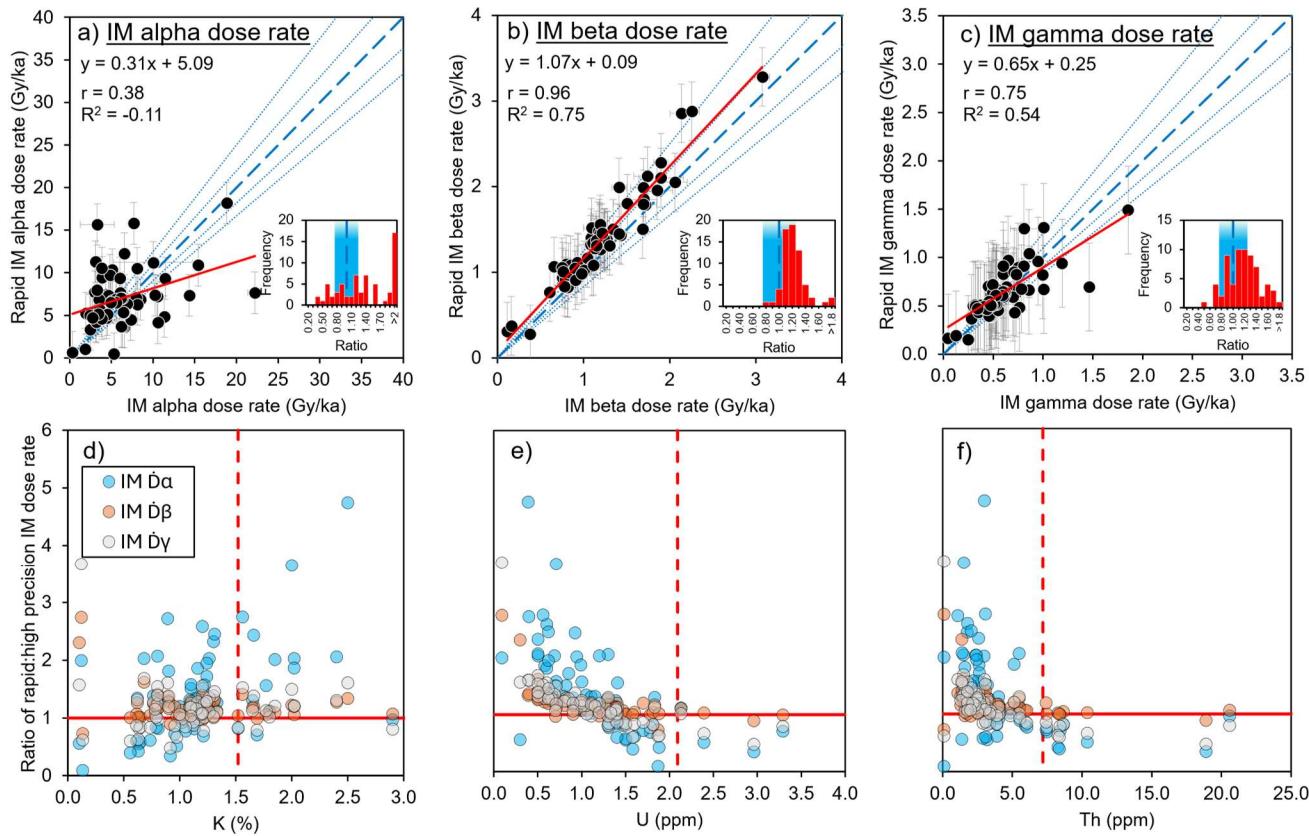

Figure 6: Results of the IM external dose rates calculated using the training-regression relationships given in Figure 4 based on an initial pXRF measurement of K concentration (yx-axes), compared with IM external dose rates calculated from K, U and Th concentrations measured using high-precision geochemistry (xy-axes): a) IM  $\dot{D}_\alpha$  results, b) IM  $\dot{D}_\beta$  results, c) IM  $\dot{D}_\gamma$  results. Pearson's correlation coefficient (r, calculated relative to the regression line, and  $R^2$  values, calculated relative to the unity line, are shown for each dataset. Dashed thick blue lines and blue shaded areas represent unity and the thinner, dashed blue lines represent  $\pm 10\%$  and  $\pm 20\%$ . The red lines denote the linear trendline for each dataset ( $n = 66$  in all cases). The standard errors of the regression slopes and intercepts are a)  $\pm 0.10$  and  $\pm 0.8069$ , b)  $\pm 0.03-0.04$  and  $\pm 0.0405$ , and c)  $\pm 0.07$  and  $\pm 0.05$ . The inset plots show frequency distributions of the ratios between rapid and high precision IM dose rates, with blue shaded areas representing  $\pm 10\%$  unity. Percentages show the proportion of central values that fall within this range and values in italics show the proportion of values that fall within  $\pm 20\%$  of unity. Panels d), e) and f) show the difference between rapid IM dose rates and high precision dose rates expressed as a ratio plotted against their concentrations of K, U and Th measured with high precision methods, respectively. For ease of interpretation, samples that resulted in negative ratios due to negative dose rates have been omitted. Horizontal red lines show unity and vertical, dashed red lines show the mean concentration of radionuclides in the training-global dataset (Table 1).

Figure 7 shows the results of using the rapid pXRF method and simplified attenuation for calculating total  $\dot{D}$  for a suite of theoretical dating targets, compared with a standard approach based on high precision geochemistry and more detailed correction using the DRAC software (Durcan et al., 2015). The rapid approach generally provides good agreement with the high precision approach, with strong positive correlations  $R^2$  values found in all cases ranging in strength from 0.48 – 0.72, relative to unity (Fig. 7).

The best agreement between the rapid and high-resolution  $\dot{D}$  determinations is found for the coarse-grained targets, which all have  $R^2$  values  $>0.80-0.67$  and the majority of at least 95% of their central rapidly-estimated total  $\dot{D}$  values fall within uncertainties of  $\pm 10\%$  of unity (Fig. 7a, b, c). Of the coarse-grained targets, the etched quartz and KF scenarios have the strongest correlations with their high-precision counterparts (r R2 = 0.9284; Fig. 7a, b) and the best agreement to the expected dose rates, with R2 values of 0.72. These show the best agreement because This result is because, due to the assumption that  $\alpha$ -irradiated portions of grains have been etched away, the only external dose rates that comprise them are IM  $\dot{D}_\beta$  and IM  $\dot{D}_\gamma$ , which have the strongest correlations with IM dose rates calculated based on high-precision geochemistry (Fig. 6b, c). For the 180-250  $\mu\text{m}$  quartz example,  $56 \pm 7\%$  of the total  $\dot{D}$  is contributed by the  $\dot{D}_\beta$ , whilst the  $\dot{D}_\gamma$  contributes  $32 \pm 5\%$  (Table 4). In the 180-250  $\mu\text{m}$  KF (etched) example, the contribution from  $\dot{D}_\gamma$  is lower as a proportion of total  $\dot{D}$  ( $22 \pm 5\%$ ) due to the contribution of internal  $\beta$  particles ( $33 \pm 1\%$ ) (Table 4). Internal dose rate contributions and the  $\dot{D}_c$  are the same for both rapidly estimated and high-precision total  $\dot{D}$  (Tables 2, 3), meaning that the reduced accuracy in estimating  $\dot{D}_\gamma$  using the rapid method is less important in the 180-250  $\mu\text{m}$  KF (etched) scenario, relative to 180-250  $\mu\text{m}$  quartz. Figure 6b also shows that the rapid method typically overestimates IM  $\dot{D}_\beta$ , leading to a tendency to slightly overestimate total dose rates relative to their high-precision counterparts (Fig. 7), given that  $\dot{D}_\beta$  makes up the largest proportion of the total dose rate in each scenario (Table 4). Overestimation of IM  $\dot{D}_\beta$  This effect explains why the latter scenario yields fewer rapidly estimated total  $\dot{D}$  values that are within  $\pm 10$  and  $20\%$  of unity with high precision total  $\dot{D}$  (70% and 88%, respectively; Fig. 7a), relative to the former scenario (85% and 98%, respectively; Fig. 7b).

By contrast, the larger the contribution of the IM  $\dot{D}_a$ , the weaker the regression correlation coefficient between rapid and high-precision total  $\dot{D}$  values. Finer grain-size scenarios (4-11  $\mu\text{m}$  polyminerals and quartz) show more scatter in comparison to 425 high-precision data, due to the incorporation of IM  $\dot{D}_a$  components to into total  $\dot{D}$  on account of them having not been etched (Fig. 7d, e). They have weaker  $R^2$  values (0.66-81 and 0.7788, respectively) and  $R^2$  values (0.48 and 0.63, respectively). However, although at least 5280% and 91% of rapidly estimated central values still fall within uncertainties of  $\pm 10\%$  of unity in both cases and at least 68% are within  $\pm 20\%$  of unity (Fig. 7d, e). In the case of the 4-11  $\mu\text{m}$  polymineral scenario,  $18 \pm 6\%$  of the total  $\dot{D}$  is contributed by  $\dot{D}_a$ , as opposed to only  $7 \pm 3\%$  in the 4-11  $\mu\text{m}$  quartz scenario (Table 4). Similarly, the 430 incorporation of IM  $\dot{D}_a$  into the total  $\dot{D}$  of 180-250  $\mu\text{m}$  KF (not etched) example likely results in the correlation with high-precision data being slightly weaker than that of the other coarse-grained scenarios that do not have IM  $\dot{D}_a$  contributions (Fig. 7c). However, the IM  $\dot{D}_a$  contribution in the 180-250  $\mu\text{m}$  KF (not etched) scenario is, on average, very small ( $3 \pm 1\%$ ), so the correlation agreement with high-precision total  $\dot{D}$  is stronger than the finer-grained examples ( $R^2$   $R2$  = 0.6780; Table 4; Fig. 7c).

435

In all scenarios, the rapid method typically overestimates total  $\dot{D}$  for values instances where the high-precision calculated dose rate is  $<\sim 5 \text{ Gy/ka}$ , as evidenced by the slopes of the regression equations being  $<1$  (Fig. 7). This is a product of the overestimation that generally results from overestimations of IM  $\dot{D}_\beta$ , as well as predicting overestimations of low IM  $\dot{D}_a$  and IM  $\dot{D}_\gamma$  values based solely on K concentration, as discussed above (Fig. 6). The convergence of the trendline with the unity line at  $\sim 5 \text{ Gy/ka}$  in each scenario suggests that higher K concentrations would result in overestimations being more likely, although beyond the range of the samples presented here. However, in all cases the slopes of the trendlines shown in Figure 7 are within two standard errors (given in the caption of Fig. 6) of the unity line. The intercepts are more dispersed, with the coarse-grained scenarios all having intercepts either within two standard errors of the unity line or very close (within 0.01 Gy/ka of two standard errors), whilst the fine-grained scenarios are not within or close to two standard errors of unity.

445

Uncertainties are larger for the rapidly estimated total  $\dot{D}$  values relative to the high precision data in all scenarios (Fig. 7). The largest sources of uncertainty in the rapidly estimated data is are the standard error RMSEs associated with the training regression relationships used to predict IM dose rates based on K concentration and the measurement uncertainties on the pXRF K concentration and its calibration. Uncertainties associated with the rapidly predicted IM dose rates are larger than the other 450 sources of uncertainty propagated in quadrature during total  $\dot{D}$  calculation arising from water content, attenuation factors, and  $\dot{D}_c$  and  $\dot{D}_i$  contributions (Tables 2, 3).

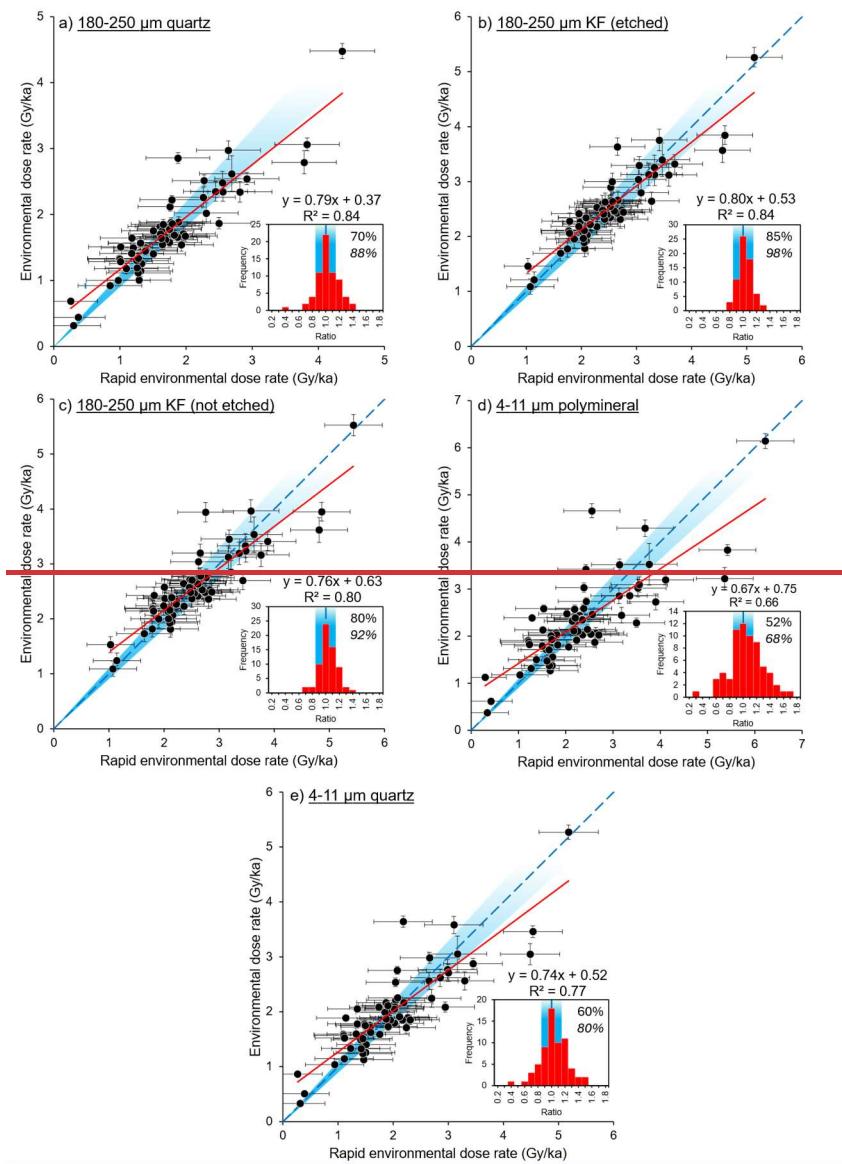

Overall, the use of a simplified set of mean attenuation factors in the rapid approach does not result in a significant loss of accuracy with respect to comparing rapid total  $\dot{D}$  to high precision  $\dot{D}$  for most dating scenarios (Fig. 7). Figure S52 455 shows total  $\dot{D}$ , calculated using IM dose rates derived from high-precision K, U and Th measurements but corrected with the simplified attenuation procedure, in comparison to the more detailed correction procedure of DRAC. All regressions have an

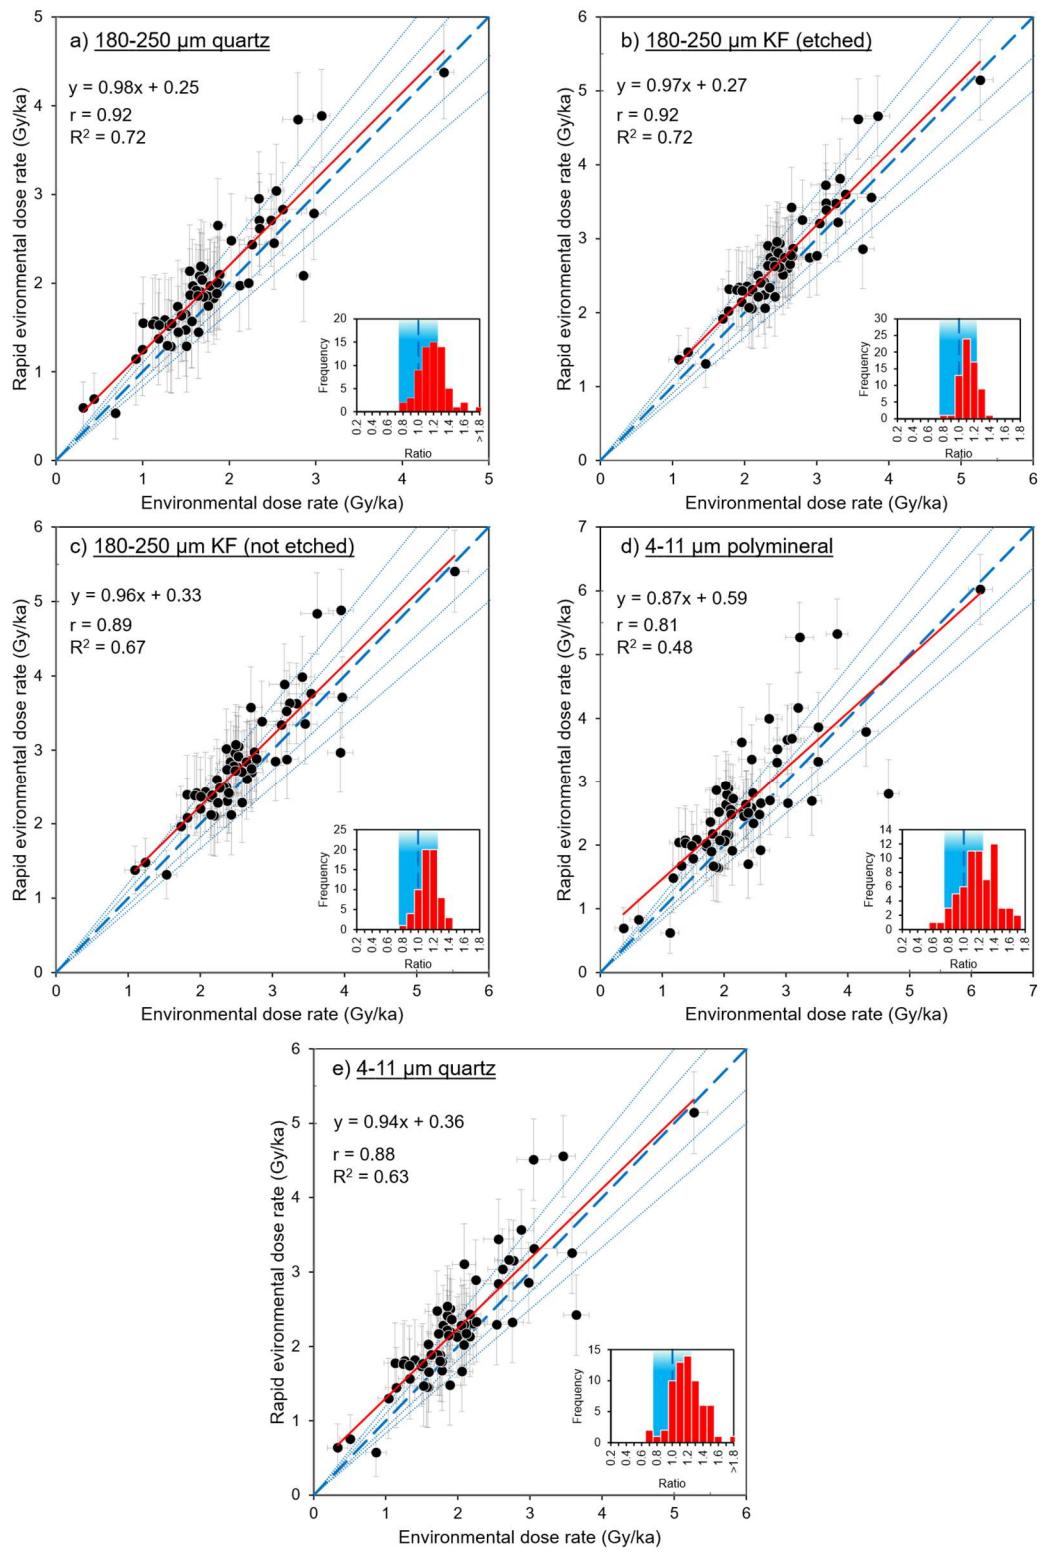

$R^2$  of >0.99 and all values are within  $\pm 10\%$  of unity (Fig. S52), demonstrating that the simplified attenuation procedure is contributing little to the discrepancies between rapidly predicted  $\dot{D}$  and high-precision  $\dot{D}$  (Fig. 7). Inaccuracies in rapidly estimated total  $\dot{D}$  are, therefore, more the product of the regression relationships derived from the [training-large radionuclide dataset](#) and [pXRF measurement uncertainty](#) (Fig. 4; Fig. 5).

Table 4: Mean percentage contributions and  $1\sigma$  uncertainties of each constituent external, corrected dose rate to the total environmental dose rate, for the theoretical dating targets shown in Fig. 7 (n=66). These contributions are from the results of high-precision total  $\dot{D}$  calculations.

Dose contribution (%)	Theoretical luminescence dating target				
	180-250 $\mu\text{m}$ quartz	180-250 $\mu\text{m}$ K-feldspar (etched)	180-250 $\mu\text{m}$ K-feldspar (not etched)	4-11 $\mu\text{m}$ polymineral	4-11 $\mu\text{m}$ quartz
$\dot{D}_\alpha$	0	0	3 $\pm$ 1	18 $\pm$ 6	7 $\pm$ 3

## 4 Discussion

### 480 4.1 Determination of K concentrations using pXRF

Estimates of potassium concentration obtained using pXRF agree very well with high-precision measurements reported for the samples analyzed (Fig. 5), demonstrating both accuracy and reliability, similar to the findings of previous studies using pXRF on sediment samples (e.g., Mejía-Piña et al., 2016; Ou et al., 2022; Zhou et al., 2023), albeit slightly underestimated in the majority of cases. We were able to detect the K concentration of 66 out of 67 samples that had a K concentration  $>0.02$  concentrations above our LOD and LOQ of 0.015 and 0.049%, respectively, with 74.65% of results falling within  $\pm 10\%$  of high-precision geochemistry measurements. This means that pXRF could be used to accurately estimate determine K contents in most sedimentary contexts with a good degree of accuracy, except where K contents are exceptionally low. Even in situations with low K contents, a non-detection could still provide useful information by estimating a maximum dose rate between 0 Gy/ka and the beta dose rate corresponding with the K value determined to be the LOD or LOQ for the specific instrument. Given that measurements take only  $\sim 90\text{ s}$  per sample, the speed of pXRF analysis enables rapid and large sample throughput in a laboratory setting.

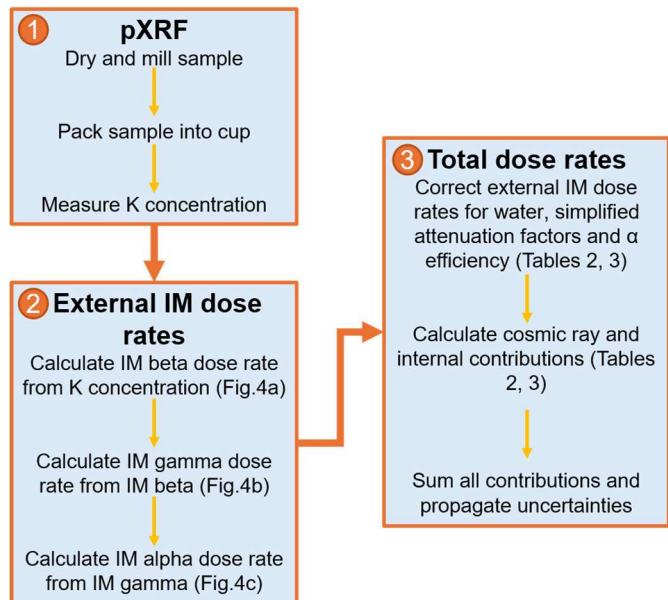

Therefore, it could be possible to make in-situ estimates of K contents for rapid dose rate estimation. However, using a pXRF system in the field could mean compromising K measurement accuracy in certain scenarios, due to complicating factors like 495 sediment moisture content and heterogeneous grain size, which cause interference (e.g., Nuchdang et al., 2018; Padilla et al., 2019; Rosin et al., 2022). For example, Padilla et al. (2019) show that pXRF underestimates multiple elemental concentrations 500 in a variety of materials with increasing moisture content, relative to expected amounts. Moisture and grain size were controlled in our laboratory experiments by drying and milling sediments prior to analysis, although it is possible that a small pestle and mortar could be taken into the field to mill sediments in situ. Numerous studies have also developed correction factors to help reduce the influence of moisture on in-situ pXRF measurements, although very site-dependent sediment characteristics mean that the success of these approaches is mixed (e.g., Stockmann et al., 2016; Ribeiro et al., 2018). Whilst our laboratory experiment serves as a necessary first step, trialing pXRF in the field for estimating dose rates in a range of different field conditions for rapidly estimating dose rates is an important future research goal. avenue.

505 An important caveat to these findings is that the precision and reliability of elemental measurement can vary between different  
pXRF instruments (Goodale et al., 2012), so it is important to ensure that instruments are calibrated using reference materials  
with established elemental concentrations. In this study, all 67 samples analyzed using the pXRF had K contents determined  
independently using high-precision methods (Fig. 5), although we additionally tested instrument accuracy and contamination  
using certified reference materials. However, for this approach to be useful in future applications, instrument calibration will  
510 be especially important when K concentrations are not independently known to provide greater confidence in the accuracy and  
reliability of pXRF measurements.

Other rapid systems for elemental analysis are also available that could be used instead of pXRF for measuring K  
concentrations in sediments. For instance, XRF core scanners provide rapid, highly spatially resolved K concentrations in  
515 sediment cores from marine and lacustrine environments (e.g., Rothwell and Croudace, 2015), which could be used  
to derive dose rates down-core. However, it is important to note that geochemical core scanning is often carried out using  
intense X-ray beams to provide additional proxies for sediment density and structure, which may destroy natural luminescence  
signals required for dating (e.g., Davids et al., 2009). Another alternative may be portable laser-induced breakdown  
spectrometers (pLIBS), which can accurately measure K concentrations with similar rapidity to pXRF (e.g., Lawley et al.,  
520 2021). Alternative approaches to rapidly measure K concentration mean that the approaches developed in this study could be  
implemented by geoscience and archaeological researchers who may be sampling for trapped charge dating studies in external  
laboratories, or have access to pOSL units, to help inform sampling strategy or provide range-finder age estimates.

#### 4.2 Rapidly estimating environmental dose rates using pXRF

Our results demonstrate that it is possible to estimate a total  $\dot{D}$  for range-finder trapped charge dating based on IM  $\dot{D}$  derived  
525 from rapidly measured K concentrations alone (Figs 6, 7). We suggest a three-step method for rapidly estimating  $\dot{D}$  using  
pXRF in a laboratory setting (Fig. 8): (1) measure the K concentration of dried, milled sediment using pXRF (or another  
method), taking the mean of triplicate measurements; (2) use the linear equations derived from the training radionuclide dataset  
(Fig. 4) to estimate external IM dose rates from pXRF K concentrations; and (3) correct IM dose rates for water content and a  
simplified set of attenuation factors and add cosmic ray and internal contributions calculated using standard procedures (Table  
530 3). Whilst this approach does not replace high-precision techniques used for accurate radionuclide and  $\dot{D}$  calculation, results  
show good agreement with  $\dot{D}$  based on K, U and Th concentrations measured by high-precision geochemistry and calculated  
using a more detailed correction procedure (Figs 6, 7). For coarse-grained luminescence dating scenarios, at least 95.70% of  
rapid estimates fall within uncertainties of  $\pm 10\%$  of unity with their high-precision counterparts, with at least 88.10% within  
uncertainties of  $\pm 20\%$  of unity (Fig. 7a, b, c).

535

**Figure 8: Flowchart showing the rapid procedure for estimating total environmental dose rates based on pXRF K measurements tested in this study.**

The simple linear regression models used for IM dose rate estimation agree well with previous studies. Ou et al. (2022) derived a linear relationship of  $IM \dot{D}_\beta = 1.02K + 0.50$  between the K contents of 61 rock slices and their  $IM \dot{D}_\beta$  (measured independently with beta counting). Our relationship of  $IM \dot{D}_\beta = 1.11K + 0.03$  derived from 1473 data points is very similar, except with an intercept much closer to the origin. Previous authors also showed that  $IM \dot{D}_\gamma$  can be predicted from  $IM \dot{D}_\beta$  using a ratio of  $\sim 0.50$  (Ankjægaard and Murray, 2007) or 0.59 (Roberts et al., 2009). If the linear relationship determined here for  $IM \dot{D}_\beta$  vs.  $IM \dot{D}_\gamma$  (Fig. 4b) is forced through the origin, then we derive a very similar ratio from the gradient of the linear trendline, which is 0.58. We found that a second-order polynomial relationship between  $IM \dot{D}_\beta$  and  $IM \dot{D}_\gamma$  was found to yield a marginally higher  $R^2$  value than the linear fit (0.94 vs. 0.93, respectively) using the equation  $IM \dot{D}_\gamma = 0.04IM \dot{D}_\beta^2 + 0.44IM \dot{D}_\beta + 0.03$ . We also found that the second order polynomial fits do not increase the strength of correlations for either the K concentration vs.  $IM \dot{D}_\beta$  or  $IM \dot{D}_\gamma$  vs.  $IM \dot{D}_\alpha$  relationships. The residual scatter in predicted  $IM \dot{D}_\gamma$  values, especially for low K concentrations (Fig. 4e). If we use a linear fit forced through the origin for these data, then the ratio of  $IM \dot{D}_\gamma$  to  $IM \dot{D}_\beta$  would be 0.58, which agrees very closely with previous findings of 0.50 (Ankjægaard and Murray, 2007) and 0.59 (Roberts et al., 2009).

555 These discrepancies between fitting parameters reported in different studies may likely be explained by different sample sizes  
556 or different sampling biases, namely the geological origin of samples. In this study, the majority of the 67 samples that we  
557 tested using this rapid approach were sourced from western North America, the radionuclide contents of which will be  
558 dependent on their specific source geology. Therefore, the results we demonstrate may not be representative of samples from  
559 other parts of the world, given differences in the geological origins of sediment. Whilst beyond the scope of this study, it will  
560 be important to test the approach proposed here on samples from other locations to determine the influence of local factors on  
561 prediction uncertainties. Similarly, testing the potential sensitivity of the models used to rapidly predict dose rates (Fig. 4) to  
562 specific regions and their different ratios of radionuclide concentrations is also an important next step. In lieu of a physical  
563 explanation for why these relationships should be fitted with a polynomial, and given the good agreement between our  
564 predicted and known total  $\dot{D}$  values (Fig. 7), we favor the simple linear regressions for the purpose of rapidly estimating  $\dot{D}$ .

565 Out of the predicted IM dose rates, IM  $\dot{D}_\beta$  is predicted with the greatest accuracy relative to the high-precision values (Fig. 6b)  
566 and IM  $\dot{D}_\alpha$  the least (Fig. 6a). This result is unsurprising, given that previous work has shown IM  $\dot{D}_\beta$  scales most strongly with  
567 K, relative to U and Th (Fig. S1; Ankjægaard and Murray, 2007), whilst IM  $\dot{D}_\alpha$  is not physically related to the K decay chain  
568 (Guerin et al., 2011). The negative intercepts in the equations relating IM  $\dot{D}_\beta$  to IM  $\dot{D}_\gamma$  and IM  $\dot{D}_\gamma$  to IM  $\dot{D}_\alpha$  means that negative  
569 estimates of IM  $\dot{D}_\beta$  and IM  $\dot{D}_\alpha$  can occur at low K concentrations ( $<0.35\%$  and  $<0.158\%$ , respectively). Whilst negative dose  
570 rates are not physically realistic, only 5% of samples in the training dataset used in this study have K concentrations  $<0.35\%$   
571 and only 21.5% are of samples in the radionuclide dataset ( $n = 1473$ ) have K concentrations  $<0.158\%$  ( $n = 1473$ ). So, negative  
572 predictions of IM  $\dot{D}_\beta$  and IM  $\dot{D}_\gamma$  are unlikely to occur in most natural sedimentary contexts. The negative intercept we observe  
573 may be the result of the natural dispersion of radionuclides in different sedimentary contexts, as well as uncertainties in their  
574 conversion to dose rates. Given that the RMSE of the IM  $\dot{D}_\gamma$  vs. IM  $\dot{D}_\alpha$  relationship is 2.40 Gy/ka (Fig. 4c), negative estimates  
575 would likely be within uncertainties of 0 Gy/ka anyway. -

576 The accuracy of rapidly measured K concentrations using pXRF and the strong relationship derived between K concentrations  
577 and IM  $\dot{D}_\beta$  could, theoretically, be used to quickly assess  $\dot{D}_\beta$  heterogeneity in un-milled sediment and rock samples (e.g.,  
578 Jankowski and Jacobs, 2018; Ou et al., 2022). The significant, positive relationship correlation between IM  $\dot{D}_\beta$  and IM  $\dot{D}_\gamma$   
579 means that this approach could also be used as a means of rapidly assessing  $\dot{D}_\gamma$  heterogeneity (Fig. 4c). However, the weaker  
580 correlation found between rapidly estimated and high-precision IM  $\dot{D}_\gamma$  (Fig. 6c) means, in practice, that this application would  
581 have limited accuracy beyond a rapid, relative assessment.

582 Despite the poorer agreement between the predicted and high-precision IM  $\dot{D}_\alpha$  values (Fig. 6a), relative to the results for IM  
583  $\dot{D}_\beta$  and IM  $\dot{D}_\gamma$ , the predicted total  $\dot{D}$  values for the theoretical dating targets in which IM  $\dot{D}_\alpha$  is a factor still yield reasonable  $R^2$   
584 values ( $>0.66$ ) relative to high precision  $\dot{D}$  values (Figs. 7c, d, e). This is because, despite the lower predictive accuracy of this  
585 method for estimating IM  $\dot{D}_\alpha$ , it typically contributes the least to total high-precision  $\dot{D}$  due to the low efficiency with which it

590 ~~irradiates mineral grains (Table 4). All three IM dose rates are typically overestimated using the relationships derived from the training dataset (Fig. 6). The IM  $\dot{D}_\alpha$  is overestimated the most, with overestimation more likely for samples with high K concentrations and/or low U and Th concentrations (Fig. 6d, e, f).~~

595 ~~Consequently, total~~<sup>The total</sup>  $\dot{D}$  predicted using our rapid method is likely to be more accurate for coarser-grained sediments (e.g., 180–250  $\mu\text{m}$ ) that have been etched than for finer-grained sediments (e.g., 4–11  $\mu\text{m}$ ) or those that have not been etched, because there is ~~no negligible~~ contribution from  $\alpha$  particles in the former scenarios (Porat et al., 2015). This means that our approach is best applied to sedimentary contexts likely to yield coarser size fractions, such as aeolian dune and fluvial deposits (e.g., Wintle, 1993; Wallinga, 2002; Srivastava et al., 2019; Durcan et al., 2019; Wolfe et al., 2023). That said, our results still show reasonable agreement for finer-grained scenarios and those where etching is not assumed, with at least ~~5280%~~ of rapidly estimated total  $\dot{D}$  values falling within uncertainties of  $\pm 10\%$  of unity with high-precision values and at least ~~6891%~~ within uncertainties of  $\pm 20\%$  (Fig. 7c, d, e). So, this approach still has useful applications to sedimentary contexts that are more likely to be dated using finer grain-size fractions, such as loess and lacustrine deposits (e.g., Singhvi et al., 2001; Roberts, 2008; Fenn et al., 2020; Burrough et al., 2022), or if the laboratory does not routinely etch coarse KF grains (Porat et al., 2015). Our approach could also be adapted to different grain-size ranges by calculating mean attenuation factors specific to the desired minimum and maximum sizes using attenuation datasets (e.g., Brennan et al., 1991; Guerin et al., 2012).

605

Lastly, this study only considers the application of this rapid  $\dot{D}$  estimation approach to sediment samples as they are most commonly the target of trapped charge dating studies. However, there is growing interest in the application of these geochronological methods to dating the burial of rock surfaces ~~and quantifying their denudation rates~~ (e.g., Sohbati et al., 2015; Jenkins et al., 2018). The pXRF approach to rapid  $\dot{D}$  estimation could be usefully applied in solid-rock contexts, especially as internal moisture content is unlikely to be important (although grain-size heterogeneity may be, e.g., Ou et al., 2022). It could offer a non-destructive approach for archaeological and culturally sensitive materials, minimizing the need for invasive sampling (e.g., Gliganic et al., 2021, 2024; Moayed et al., 2023).

## 5 Conclusions

615 This study provides a proof of concept that a total environmental dose rate,  $\dot{D}$ , can be estimated using a pXRF measurement of K concentration alone, regression relationships provided by a large training radionuclide dataset and a simplified set of attenuation factors. This approach is rapid and does not require expensive, specialist facilities. Whilst it is not a replacement for high-precision means of determining  $\dot{D}$ , it could support trapped-charge dating studies by offering a means of estimating rapid, range-finder  $\dot{D}$  values to help inform sampling strategy and generate initial age estimates.

620 The [training-radionuclide](#) dataset utilized is comprised of 1473 sediment samples from around the world with radionuclide concentrations (K, U, Th) measured using high-precision geochemistry. These data represent a large variety of different sedimentary and dosimetry contexts and emphasize the utility of large sample analysis to trapped charge dating studies. The linear regression relationships established based on the [training-radionuclide](#) dataset between K concentrations and IM  $\dot{D}_\beta$ , IM  $\dot{D}_\beta$  and IM  $\dot{D}_\gamma$ , and IM  $\dot{D}_\gamma$  and IM  $\dot{D}_\alpha$  provide a means of rapidly predicting IM dose rates based on an initial input of K  
625 concentration, with strong positive correlations found in all cases.

We found that pXRF provides a rapid and reasonably accurate means of measuring the initial K input to these linear equations, in a controlled laboratory context. We were able to measure K concentrations  $>0.02\%$  for diverse sediment samples, representing [99% of 94% of the range of](#) K concentrations included in the global [training-radionuclide](#) dataset. However, 630 questions remain about the accuracy of this method if applied in a field context where grain size and moisture may influence results. The [linear](#) relationships used to derive IM dose rate estimates from pXRF K measurements were able to predict IM  $\dot{D}_\beta$  with the greatest accuracy with respect to IM  $\dot{D}_\beta$  calculated using high-precision K, U and Th data, whilst IM  $\dot{D}_\alpha$  was predicted least accurately. Despite inaccuracies in IM  $\dot{D}_\alpha$  estimation, good agreement is demonstrated for a range of theoretical 635 luminescence dating targets between total  $\dot{D}$  values calculated using rapidly estimated IM dose rates and simplified attenuation procedures, with respect to those calculated using high-precision radionuclide concentrations and more complex attenuation. Agreement between these rapidly predicted dose rates and those calculated with high-precision radionuclides is  $>7095\%$  and  $>88\%$  within [uncertainties of  \$\pm 10\$  and  \$20\%\$  of unity, respectively](#), for coarse-grained quartz and KF scenarios where  $\dot{D}_\alpha$  is assumed to be negligible. Even when there are IM  $\dot{D}_\alpha$  contributions to the overall dose rate,  $>5280\%$  and  $6891\%$  of rapidly 640 predicted results fall within [uncertainties of  \$\pm 10\$  and  \$20\%\$  of unity with high-precision values, respectively](#). As such, this pXRF-based approach to rapidly estimating dose rates shows promise in a variety of sedimentary settings, even for fine-grained sediments where  $\alpha$  particles are likely to contribute more significantly to the  $\dot{D}$  of dating targets.

## Data availability

All data are available in the supplementary .csv files.

## Author contribution

645 SW was responsible for conceptualizing the project, constructing the [training-radionuclide](#) dataset, carrying out laboratory measurements, data analysis and the preparation of all figures and the initial draft of this manuscript, under the supervision of MD and OL and with the input of MS and JD. OL and MS provided the sediment samples analyzed in this study. MD, OL, JD and MS provided feedback on the [training-radionuclide](#) dataset and laboratory measurements, as well as editing the manuscript.

## Competing interests

We show that portable X-ray fluorescence can be used to rapidly (c. 90 s) estimate the environmental dose rates used to calculate burial ages in trapped charge dating studies. This procedure involves inputting a measurement of potassium concentration into a set of simple linear equations, defined by a large, training-radionuclide dataset. Results show good agreement with high-precision methods. Our rapid method will help to quickly generate burial age estimates.
