20
21 **Abstract:** Modeling the coupled human–natural systems (CHANS) is vital for
22 understanding human–natural interactions and achieving regional sustainability,
23 offering a powerful tool to alleviating human–water conflicts, ensuring food security,
24 thereby supporting the region’s pathway toward sustainable development. However, the
25 scarcity of regional-scale CHANS models constrains progress in practical applications
26 for regional sustainability. The Yellow River basin (YRB) is an ideal region for

27 modeling regional CHANS due to its closely coupled human and natural systems,
28 which are stressed by water and ecosystem fragility. Here, we developed the CHANS-
29 SD-YRB model using the System Dynamics approach, integrating 10 sectors essential
30 for modeling human-water interactions of the basin, including five human sectors
31 (Population, Economy, Energy, Food, and Water Demand) and five natural sectors
32 (Water Supply, Sediment, Land, Carbon, and Climate). The model can simulate
33 evolution and feedbacks of the YRB CHANS annually at provincial and sub-basin
34 scales, while conserving hydrological connectivity between sub-basins. The model can
35 accurately reproduce historical CHANS dynamics, achieving strong quantitative
36 agreement with historical data ($R > 0.95$ for human sectors and $R > 0.7$ for natural
37 sectors), which supports its applicability for scenario analyses and future projections.
38 We applied the model to explore human–natural system dynamics under a future
39 baseline scenario, assuming the continuation of existing policies and climate projection
40 under middle of the road scenario (SSP–RCP 2-4.5). The future projections (2021-2100)
41 indicate that achieving sustainable development in the YRB will remain challenging,
42 though economic growth and food security are expected to improve. Emerging issues,
43 such as ecological–human water trade-offs, labor shortages, reduced sediment load, and
44 limited carbon absorption capacity, may hinder regional long-term sustainability.

45 **Keywords:** coupled human-natural systems, regional modeling, system dynamics,
46 the Yellow River Basin

47 **1 Introduction**

48 Coupled human and natural systems (CHANS) emphasize the reciprocal feedback
49 and co-evolution between human and natural systems, offering an integrated framework
50 for diagnosing complex problems and guiding sustainable development (Fu and Li,
51 2016). By capturing dynamic interactions of interconnected components, CHANS
52 theories and models enable more effective policies and interventions that align
53 ecological integrity with socioeconomic progress (Motesharrei et al., 2016; Verburg et
54 al., 2016). Numerous integrated modelling approaches have been developed to simulate

55 human–natural interactions at the global scale. These include system dynamics-based
56 integrated assessment models (IAMs), such as ANEMI (Breach and Simonovic, 2021),
57 FeliX (Rydzak et al., 2013; Ye et al., 2024), and FRIDA (Rajah et al., 2025), process-
58 based and optimization-based IAMs (Vaidyanathan, 2021), and Earth system models
59 with synchronously coupled human components, such as E3SM-GCAM (Di Vittorio et
60 al., 2025) and integrated Earth system models (iESMs) (Jain et al., 2022). These models
61 effectively characterize human–natural interactions at the global scale, and have been
62 applied to assess the impacts of climate change on human society (e.g., agriculture
63 (Monier et al., 2018), economic damage (Wang et al., 2020b), fatalities increase and
64 welfare loss (Dottori et al., 2018)), and humans’ feedback on the Earth system, such as
65 those from climate mitigation on water and food security (Cheng et al., 2022; Fujimori
66 et al., 2022).

67 Currently, most CHANS models are at the global scale (Calvin and Bond-
68 Lamberty, 2018) with much fewer regional models. While global modeling research
69 has deepened our knowledge of dynamic feedbacks among Earth’s spheres and system
70 evolution under climate change, sustainability challenges often manifest at regional
71 scales, where social and ecological dynamics are more intricately intertwined (Liu et
72 al., 2007). Compared to global CHANS, regional CHANS are open systems that
73 continuously exchange energy and materials with other regions and the global system,
74 e.g., water resources and electricity transfers (Dobbs et al., 2023; Zhang et al., 2022a)
75 and trade (Ristaino et al., 2021), resulting in pericoupling and telecoupling of different
76 systems (Liu, 2017). Besides, regional CHANS are shaped by more immediate and
77 complex human influences and stressors, such as urban expansion (van Vliet, 2019),
78 ecological protection (Xu et al., 2017; Yang et al., 2022), and water resource regulation
79 policies (diversion and allocation) (Song et al., 2024), which alter regional CHANS
80 dynamics. Due to their diverse ecological and socioeconomic resilience, regional
81 CHANS exhibit heterogeneous responses to external weather events and climate
82 change, as evidenced by differing responses in crop yield (Hasegawa et al., 2021) and

83 economic production to extreme heat and warming (Waidelich et al., 2024a).
84 Furthermore, the coarse spatiotemporal resolution of global models limits their capacity
85 to support effective decision-making for regional development (X. Li et al., 2018). As
86 such, advancing regional CHANS modeling is essential for informing adaptive
87 strategies in the face of growing regional environmental and societal pressures.

88 To address this limitation, many regional CHANS models have been developed at
89 various regional scales (e.g., national, basin, and urban) using System Dynamics (SD)
90 and agent-based modeling (ABMs) techniques. Notable examples include the ANIME-
91 Yangtze model (Jiang et al., 2022), the T21-China (Qu et al., 2020), and the iSDG-
92 Australia model (Allen et al., 2019), all based on SD, the Jordan Water Model (Yoon et
93 al., 2021) with its core on ABM, as well as integrated models in the San Juan River
94 Basin (Hyun et al., 2019) and the Heihe River Basin (Li et al., 2021). These models are
95 designed to capture finer-scale dynamics and region-specific human–natural
96 interactions, since they embed localized characteristics (e.g., fishing ban, reservoir
97 operation strategies, demographic policies, transboundary flows) and account for
98 heterogeneity overlooked by global models. As a result, regional CHANS models offer
99 stronger policy relevance, providing actionable insights for national, basin, and urban
100 decision-making, and advancing CHANS research across multiple scales.

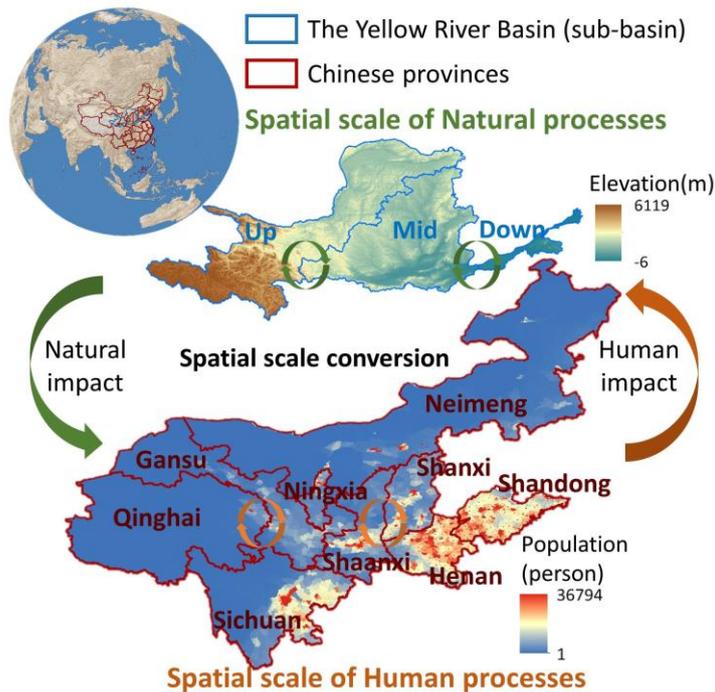

101 The Yellow River Basin (YRB) in China is one of the regions where conflicts
102 between human and natural systems are most acute and complex, particularly in terms
103 of human–water relations, due to the severe imbalance between socioeconomic
104 development and natural hydrological, ecosystem processes. The YRB faces severe
105 water stress, with the water resource utilization rate exceeding 80% (Feng and Zhu,
106 2022; Zhang et al., 2022b). Intensive water extraction has triggered a series of
107 ecological and environmental issues, including flow interruptions, water pollution, and
108 declining groundwater levels, all of which in turn constrain socioeconomic
109 development. The Yellow River traverses the Loess Plateau (Zhu et al., 2019), where
110 severe soil erosion makes the Yellow River one of the most sediment-laden rivers

111 globally (Fu et al., 2011; Yin et al., 2021). The pronounced spatial and temporal
112 variability in streamflow and sediment load leads to significant riverbed aggradation,
113 frequent flooding, and disruption of agricultural production and other livelihood
114 activities (Miao et al., 2016). Due to internal hydrological connectivity, sub-basins are
115 highly interconnected and are susceptible to upstream influences. Upstream water
116 overuse diminishes downstream availability (Wei et al., 2023), a factor that played a
117 major role in flow interruptions during the 1990s (Changming and Shifeng, 2002; Wang
118 et al., 2019). Ecological challenges differ across the subbasin, with the upstream facing
119 ecosystem degradation and limited water retention (Ning et al., 2022), the midstream
120 characterized by soil erosion and large-scale ecological restoration (Fu et al., 2011), and
121 the downstream focusing on wetland conservation (Fu et al., 2023). Policy measures
122 aimed at ecological restoration, such as afforestation and cropland conversion, have
123 increased vegetation cover, reduced sediment loads but also decreased runoff,
124 exacerbating water scarcity (Feng et al., 2016; Wang et al., 2016). These interlinked
125 dynamics underscore the YRB as a complex coupled human–natural system, where
126 addressing environmental challenges requires an integrated, systems-oriented approach.

127 The existing models for the YRB are typically designed for specific problems with
128 a narrow application focus and only represent a limited set of human and natural
129 components within the CHANS. These include limited nature-to-human impact
130 pathways, e.g., low flows threatening farmers’ livelihoods (Liu et al., 2008), the damage
131 of floods and droughts on agriculture (Zhang et al., 2015), as well as human-to-nature
132 impact pathways, e.g., effects of ecological restoration policy on hydropower and
133 water–sediment–carbon dynamics (Wu et al., 2025; Yan et al., 2024), and the impacts
134 of irrigation water-saving and salinity-control practices on crop yield and water
135 productivity (Wu et al., 2023). These models focus on isolated components of CHANS,
136 with limited consideration of fully coupled human–natural interactions, which limits
137 their capacity to represent full human–natural interactions and support regional
138 decision-making.

139 To address the gap in CHANS modeling for the YRB, following our previously
 140 proposed CHANS modeling framework for the basin (Sang et al., 2025b), we
 141 implemented the framework to develop the coupled human and natural systems model
 142 for the YRB (CHANS-SD-YRB) using the System Dynamics approach. Through
 143 dynamic interaction with policies, climate change, human activities, and environmental
 144 feedbacks, the CHANS-SD-YRB model provides a platform for predicting system
 145 dynamics, conducting scenario analyses, evaluating policies, and optimizing water-
 146 food-carbon synergies. This study ~~offers~~presents a detailed description and
 147 methodological documentation of the model, offering both theoretical and practical
 148 insights ~~for advancing~~to advance regional CHANS modeling and ~~promoting~~promote
 149 sustainable development in the YRB.

150 **2 Description of the CHANS-SD-YRB**

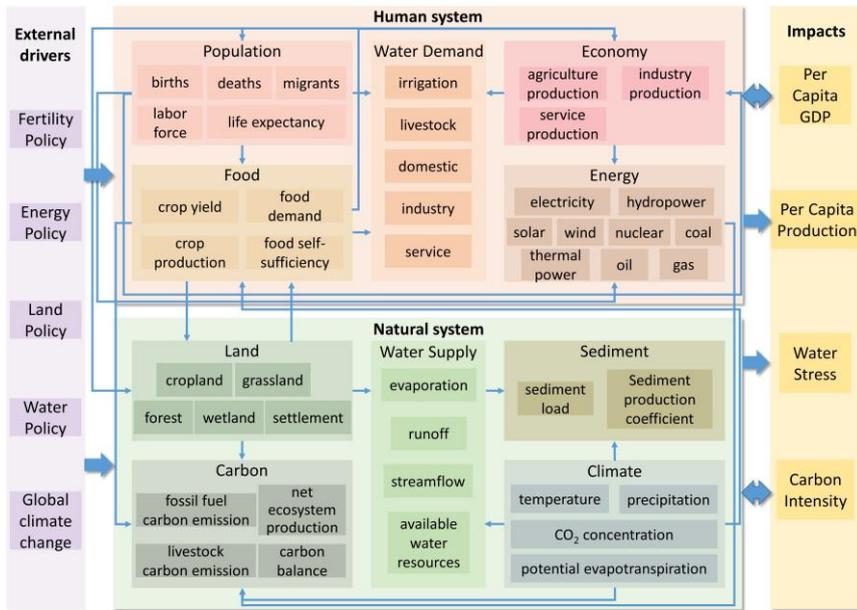

151
 152 Fig.1 Geolocation of the Yellow River Basin and boundary of the natural and human

153 processes in the CHANS-SD-YRB model. Natural processes are simulated at the sub-
154 basin scale (base map: elevation), and human processes at the provincial scale across
155 nine provinces (base map: population density in 2020).

156 We developed the CHANS-SD-YRB based on system dynamics, a method well-
157 suited for capturing complex system behaviors characterized by nonlinearity, multi-
158 level structures, and feedback loops (Forrester, 1968; Richardson, 2011). The model
159 was constructed and implemented using the VENSIM DSS (Ventana Systems, 2023)
160 software platform, operating on an annual time step. The CHANS-SD-YRB simulates
161 both human and natural processes for historical simulations (1981–2020) and future
162 projections (2021–2100). Human processes are simulated at the provincial scale,
163 covering the nine provinces along the Yellow River (Qinghai, Sichuan, Gansu, Ningxia,
164 Neimeng, Shaanxi, Shanxi, Henan, and Shandong), while natural processes are
165 simulated at the sub-basin scale (up-, mid-, and downstream) (Fig.1). The model is
166 designed to capture the various interactions within and between different components
167 of human system and natural system across administrative and hydrological units. The
168 spatial scale conversion between provincial and sub-basin levels relies on weights (e.g.,
169 the proportion of sub-basin-level values to provincial total values) derived from
170 historical high-resolution gridded datasets of human-related variables. These weights
171 enable disaggregation of provincial outputs to the sub-basin level (see Supporting
172 Information S4 for details). Given the availability of gridded data for human processes
173 and the strong correlations among relevant variables, gridded population and GDP data
174 were used as proxies to disaggregate demographic variables and economic and human
175 carbon emissions, respectively, from provincial-level to the sub-basin scale (Table S3).

176 **2.1 Model structure**

177
178 Fig.2 Structure of the CHANS-SD-YRB, which shows sectors of human and natural
179 systems, their key processes and interactions.

180 Drawing on the modeling framework of CHANS in the YRB (Sang et al., 2025b),
181 we designed the CHANS-SD-YRB structure (Fig. 2), including five sectors related to
182 human society (*Population, Economy, Energy, Food, and Water Demand*), and five
183 sectors related to natural ecosystem (*Water Supply, Sediment, Land, Carbon, and*
184 *Climate*).

185 These sectors are interconnected to represent various human-natural interactions
186 as summarized below. Key interactions among human system modules are summarized
187 below. The *Population* sector affects food demand (*Food*), residential water use (*Water*
188 *Demand*), household electricity and gas consumption (*Energy*), and settlement land area
189 (*Land*). The sector also interacts dynamically with the *Economy* sector, where economic
190 output influences deaths and migrants, while the labor force, in turn, drives economic
191 production. The *Economy* sector drives energy uses (electricity, coal, oil, and gas use)

192 from *Energy*, as well as industrial and service water withdrawal from *Water Demand*.
193 The gross agricultural production in the *Economy* is made up of crop and livestock
194 production (*Food*). The *Energy* sector produces fossil fuel emissions in the *Carbon*
195 sector. The *Food* sector is affected by the *Land* and *Climate* sector, and it also
196 determines irrigation water withdrawal (*Water Demand*) and livestock-related
197 emissions (*Carbon*). Additionally, the *Food* sector interacts closely with the *Land* sector,
198 where crop production depends on cropland area, which, in turn, is influenced by food
199 self-sufficiency. The *Water Demand* sector affects streamflow in the *Water Supply*
200 sector through consumptive water use.

201 The key interactions among natural system modules are listed below. The *Land*
202 sector influences evapotranspiration in the *Water Supply* sector through vegetation
203 coverage, and it influences carbon absorption in *Carbon* sector through land use area.
204 The carbon absorption is also affected by climatic variables including temperature,
205 precipitation, and CO₂ concentration. Similarly, runoff in the *Water Supply* sector is
206 affected by precipitation, precipitation intensity (mm/h, the rate of rainfall within one
207 hour calculated from daily data), and potential evapotranspiration. Streamflow
208 influences sediment dynamics in the *Sediment* sector together with the *Climate* sector.

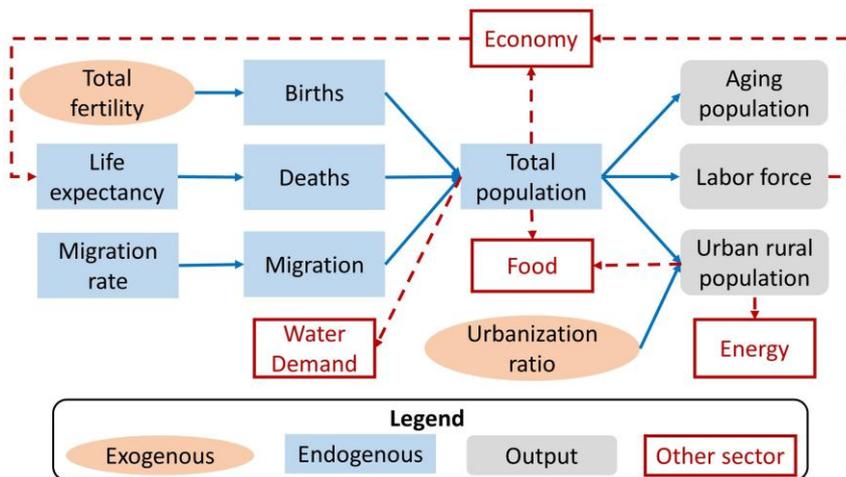

209 In addition, the CHANS dynamics in the YRB are modulated by external drivers,
210 including policies and global climate change that affect various modeled processes (e.g.,
211 fertility, energy, land use, and water). With comprehensive representation of CHANS
212 processes and their interactions, the CHANS-SD-YRB model is capable of generating
213 integrated indicators to assess the state of the coupled system, such as per capita GDP,
214 per capita food production, water stress, and carbon intensity. These indicators not only
215 serve as evaluation metrics but also feed back to influence the internal dynamics of the
216 human–natural system in the YRB.

217 **2.2 Sector description**

218 The CHANS-SD-YRB model focuses on the essential human–natural processes in
219 the YRB, with a particular emphasis on human–water interactions. To this end, it has a

220 comprehensive representation of the full range of natural and human processes that
 221 influence water use and supply. Formulation of each sector aims to explicitly account
 222 for cross-sectoral interactions as fully as possible while remaining sufficiently simple
 223 to be implemented within the SD software. Considering data availability and the spatial
 224 scales of process, human sectors (*Population, Economy, Energy, Food, and Water*
 225 *Demand*) are simulated at the provincial level, while natural sectors (*Water Supply,*
 226 *Sediment, Land, Carbon, and Climate*) are simulated at the sub-basin level within the
 227 YRB. Next, we describe each sector and its key formulation and provide full details in
 228 Supporting Information S2.

229 **2.2.1 Population**

230
 231 Fig.3 Structure of the *Population* sector. Blue lines indicate connections inside the
 232 sector, red dotted lines indicate connections with other sectors.

233 Population dynamics are driven by births, deaths, and migration (Fig. 3). Births
 234 are calculated based on exogenous total fertility rates derived from historical data
 235 (Equation S2) to reflect the strong influence of China's Family Planning Policy. Deaths
 236 are determined by the life expectancy, which is modeled as a function of human well-
 237 being (Equations S3-S6). Migration is calculated based on historical statistical data and
 238 per capita GDP differences between YRB and the national average level (Equations S7-

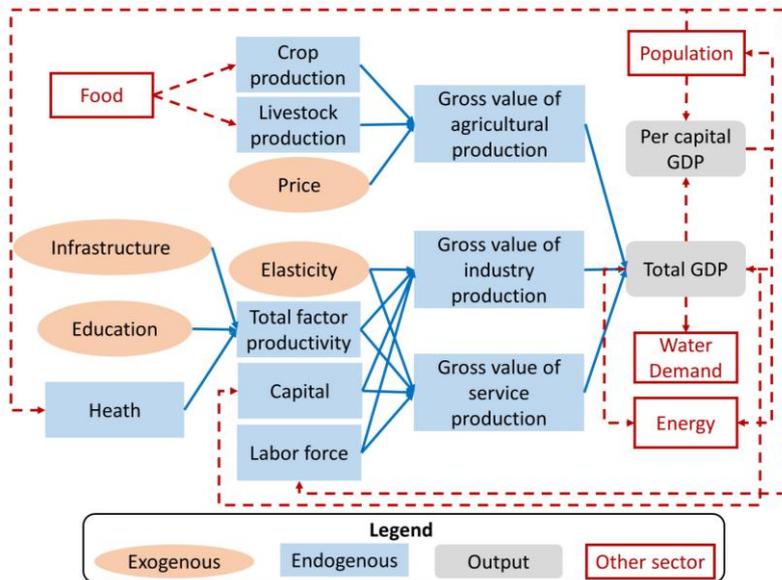

239 S8). The total population is characterized by age and gender with exogenous
 240 urbanization ratios. The output of *Population* sector drives *Economy*, *Energy*, *Food*,
 241 and *Water Demand* sectors through labor force, urban and rural populations.

242 The key variable, total population, is modeled using the age-structured
 243 mathematical method (Kemei et al., 2024), which categorizes individuals by one-year
 244 age group and gender (Equation 1),

$$245 \text{Pop}_{g,a} = \text{IniPop}_{g,a} + \begin{cases} \int (B_{g,a} + NM_{g,a} - D_{g,a})dt, & a = 0 \\ \int (\text{Pop}_{g,a} + NM_{g,a} - D_{g,a})dt, & 1 \leq a \leq 99, a = 100 \text{ and over} \end{cases} \quad (1)$$

247 where *Pop* is population, subscript *g* and *a* are gender (*g* = M is male, *g* = F is female)
 248 and age (*a* = 0-100 and over); *IniPop*_{*g,a*} is the population in the initial year, *B*_{*g,a*} is the
 249 births, *D*_{*g,a*} is the deaths, and *NM*_{*g,a*} is the net migrants (i.e., immigrants – emigrations).

250 2.2.2 Economy

251
 252 Fig.4 Structure of the *Economy* sector. Blue lines indicate connections inside the
 253 sector, red dotted lines indicate connections with other sectors.

254 The *Economy* sector simulates production activities in agriculture, industry, and

255 services, which in turn drive changes in the *Population, Energy, and Water Demand*
256 sectors (Fig. 4).

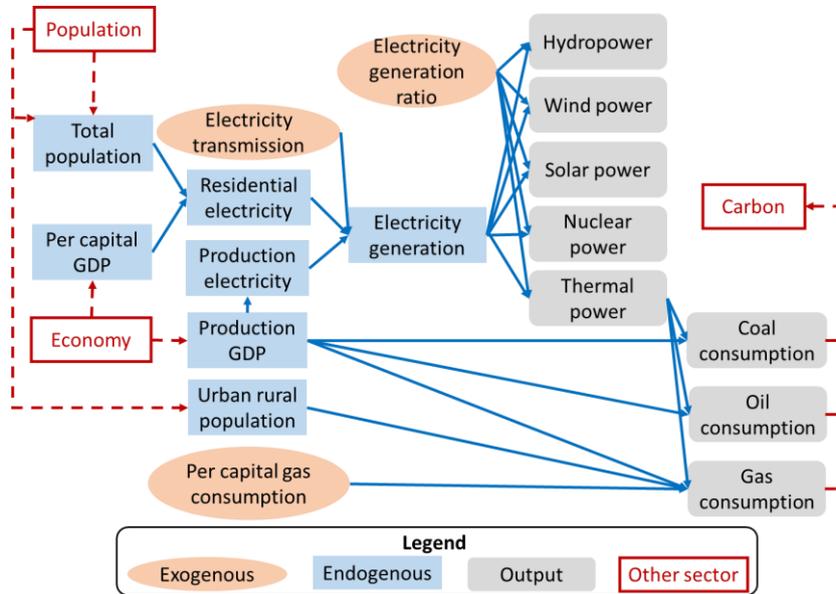

257 The gross product of industry and services is calculated using the Cobb-Douglas
258 production function (Cobb and Douglas, 1928) to account for multiple factors in the
259 economy (Equation 2). Exogenous variables (infrastructure, education, and elasticity),
260 and endogenous variables (health and labor force) from the *Population* sector
261 (Equations S10-S21) all affect the gross domestic product in industry and service
262 (GDP_s),

263
$$GDP_s = IniGDP_s \times TFP_s \times \left(\frac{L_s}{IniL_s}\right)^{1-\alpha_s} \times \left(\frac{K_s}{IniK_s}\right)^{\alpha_s} \quad \text{---(2)}$$

264 where subscript s represents industry and service, $IniGDP_s$ is the initial GDP; TFP_s is
265 the total factor productivity calculated from exogenous (infrastructure, education, and
266 elasticity) and endogenous variables (health and labor force) (Equations S10-S13); L_s
267 represents the labor force and $IniL_s$ is its initial value (from *Population* sector); α_s and
268 $1-\alpha_s$ are capital and labor elasticities from T21-China (Qu et al., 2020) and calibrated
269 using historical data; K_s and $IniK_s$ refer to the capital stock and its initial level.

270 Gross agricultural production includes crop and livestock production from *Food*
271 sector, calculated by their respective prices (Equations S22-S23).

272 **2.2.3 Energy**

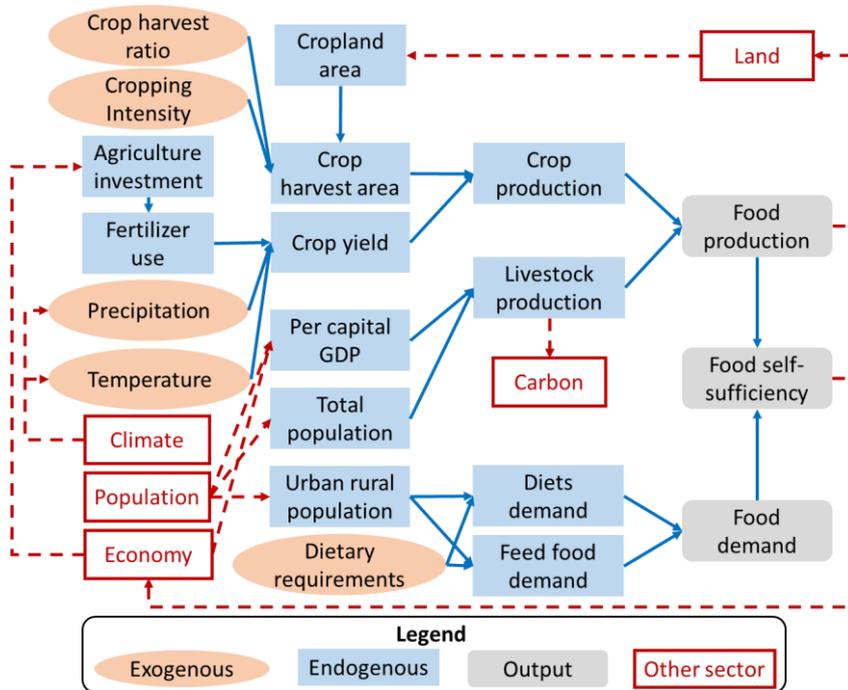

273
274 Fig.5 Structure of the *Energy* sector. Blue lines indicate connections inside the sector,
275 red dotted lines indicate connections with other sectors.

276 The *Energy* sector simulates production, consumption, and the structure of the
277 energy system, encompassing fossil fuels (coal, oil, and gas) and electricity (Fig. 5).
278 Energy production and consumption are always balanced in this sector. Electricity
279 generation is divided into residential and production uses, the former is estimated from
280 the linear fit of historical per capita GDP and residential demand, and the latter is
281 calculated using GDP and electricity intensity data from the China Energy Statistical
282 Yearbook (NBSC, 2020a) (Equations S24-S25). Cross-provincial electricity
283 transmission is also incorporated according to the same yearbook. The shares of
284 electricity generated from thermal, hydro, wind, solar, and nuclear sources are
285 determined by exogenously specified ratios, as reported in the China Energy Statistical
286 Yearbook (NBSC, 2020a). The fossil fuel consumption by economic production of
287 industry and service sectors is modeled as a linear function of sectoral GDP based on
288 historical data (Equations S26-S28). It combines with fossil fuel consumption for

289 electricity generation and residential gas consumption to drive carbon emissions in the
 290 *Carbon* sector.

291 **2.2.4 Food**

292
 293 Fig.6 Structure of the *Food* sector. Blue lines indicate connections inside the sector,
 294 red dotted lines indicate connections with other sectors.

295 The *Food* sector simulates the production of livestock and crops, and food demand,
 296 and these productions directly affect gross agricultural production in the *Economy*
 297 sector (Fig. 6). Livestock production ($Livestock_{pro}$) is calculated by an empirical
 298 function, driven by economic development and population growth (Equation 3),

299
$$Livestock_{pro} = Pop \times \left(Para_{GL1} + (Para_{GL2} - Para_{GL1}) \times \frac{PC_{GDP}}{PC_{GDP} + Const_{GL}} \right) \quad (3)$$

300 where $Para_{GL1}$, $Para_{GL2}$ and $Const_{GL}$ are parameters obtained by fitting the historical
 301 per capita meat production and per capita GDP (PC_{GDP}) data.

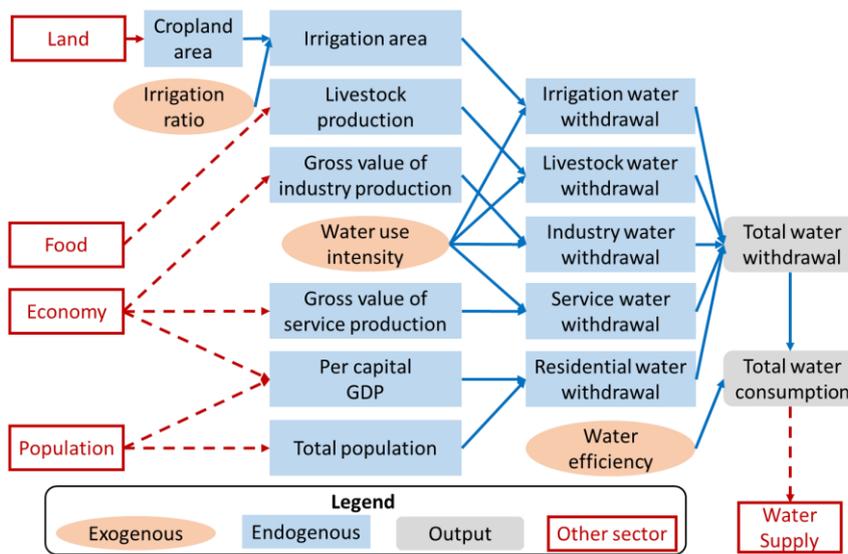

302 Crop production ($Crop_{pro}$) is determined by the yield ($Yield_c$) and harvest area (PA_c)
 303 of seven major crop types (subscript c): rice, wheat, corn, soybeans, cotton, potatoes,

304 and oil crops (Equation 4). The harvest area is influenced by cropland area from the
 305 *Land* sector, exogenous cropping intensity and crop harvest ratio. Crop yields are
 306 positively affected by agricultural investment from the *Economy* sector, along with
 307 effects of precipitation, temperature, and CO₂ concentration from the *Climate* sector
 308 (Equations S30-S36).

309
$$Crop_{pro} = \sum_{c=1}^7 Yield_c \times PA_c \quad \text{--- (4)}$$

310 Food demand encompasses both staple and feed grain demand, which are
 311 determined by population size from *Population* sector and dietary patterns (Equations
 312 S37-S41).

313 **2.2.5 Water Demand**

314
 315 Fig.7 Structure of the *Water Demand* sector. Blue lines indicate connections inside the
 316 sector, red dotted lines indicate connections with other sectors.

317 The *Water Demand* sector simulates water withdrawal (*WW*) and consumption
 318 (*WC*) across multiple uses—irrigation, livestock, industry, services, and residential—
 319 in the nine provinces of the YRB (Fig. 7). Water consumption is derived as the product
 320 of water withdrawal and water use efficiency reported in the Water Resources Bulletin
 321 (YRCCMWR, 2020) (Equations S42-S43), which affects the *Water Supply* sector.

322 Irrigation water withdrawal (WW_{irr}) is estimated through a physically-based
 323 function of exogenous irrigation water use intensity (WWI_{irr}), cropland irrigation ratios
 324 (IR) from the China Agricultural Yearbook (MAARA, 2020), and cropland area
 325 ($Area_{Cropland}$) provided by the *Land* sector (Equation 5).

326
$$WW_{irr} = WWI_{irr} \times Area_{Cropland} \times IR \quad \text{---(5)}$$

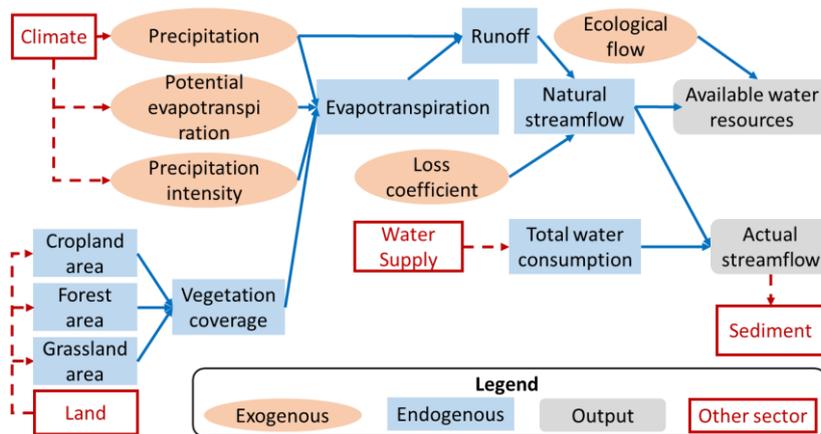

327 The water withdrawal for livestock, industry, and services is also driven by
 328 exogenous sectoral water use intensities collected from the China Statistical Yearbook
 329 and National Long-term Water Use Dataset of China (Zhou et al., 2020), in combination
 330 with livestock production from the *Food* sector, economic output from the *Economy*
 331 sector (Equations S45-S48).

332 Residential water withdrawal (WW_{res}) is derived from a non-linear empirical
 333 function of economic development and population growth with an upper limit of per
 334 capita domestic water use (Flörke et al., 2013) because water demand per person cannot
 335 increase indefinitely (Equation 6),

336
$$WW_{res} = Pop \times \left(Para_{GD1} + (Para_{GD2} - Para_{GD1}) \times \frac{PC_{GDP}}{PC_{GDP} + Const_{GD}} \right) \text{---(6)}$$

337 where $Para_{GD1}$, $Para_{GD2}$, and $Const_{GD}$ are parameters obtained by fitting the historical
 338 per capita domestic water use with per capita GDP (PC_{GDP}).

339 **2.2.6 Water Supply**

340

341 Fig.8 Structure of the *Water Supply* sector. Blue lines indicate connections inside the
 342 sector, red dotted lines indicate connections with other sectors.

343 The *Water Supply* sector simulates runoff, discharge, and their changes in each
 344 sub-basin (Fig. 8). Runoff (R) is determined by precipitation (Pre) and
 345 evapotranspiration (ET) based on the water balance principle derived from the Budyko
 346 equation, which is suitable for non-humid regions of China (Yang et al., 2009)
 347 (Equation 7).

$$348 \quad R = Pre - ET \quad (7)$$

349 The ET is calculated by various exogenous climate variables from the *Climate*
 350 sector, and vegetation coverage from the *Land* sector (Equations 8-9, S51-S53),

$$351 \quad ET = \frac{PET \times Pre}{(Pre^n + EP^n)^{\frac{1}{n}}} \quad (8)$$

$$352 \quad n = Para_{E1} \times \left(\frac{Ks}{PI}\right)^{Para_{E2}} \times FVC^{Para_{E3}} \times e^{Para_{E4} \tan \beta} \quad (9)$$

353 where PET is potential evapotranspiration at sub-basin, from the *Climate* sector; n is a
 354 parameter reflecting the basin landscape characteristics, related to saturated hydraulic
 355 conductivity (Ks), precipitation intensity (PI), average slope (β), and fraction of
 356 vegetation coverage (FVC); $Para_{E1}$, $Para_{E2}$, $Para_{E3}$, and $Para_{E4}$ are parameters fitted
 357 from historical data.

358 Runoff and the loss coefficient (defined by the ratio of natural streamflow to runoff)
 359 determine the natural streamflow due to the water loss during the confluence process
 360 (Equation S54). Natural streamflow and ecological flow constraints define the upper
 361 limit of available water resources. By integrating human water consumption from the
 362 *Water Demand* sector across sub-basins, the model calculates the actual streamflow
 363 (Equations S55-S57). Actual streamflow is transferred through hydrological
 364 connectivity from upstream to midstream and then to downstream, ultimately reaching
 365 the sea, which governs sediment transport processes within the *Sediment* sector.

366 2.2.7 Sediment

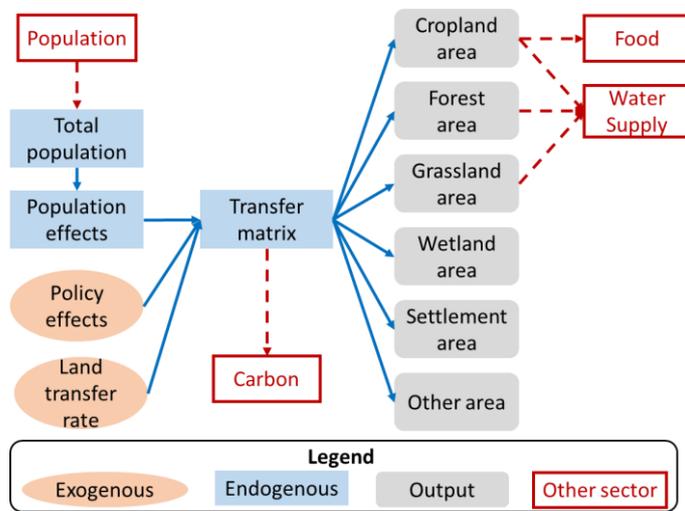

367 The *Sediment* sector estimates sediment load (Sed) for each sub-basin using an

368 empirical model in the literature (Yin et al., 2023b), which links actual streamflow from
 369 the *Water Supply* sector to sediment transport,

370
$$Sed = Para_{SS} \times AS + Const_{SS} \quad \text{--- (10)}$$

371 where $Para_{SS}$ and $Const_{SS}$ are derived from linear fitting of historical hydrological
 372 station data on actual streamflow and sediment load.

373 **2.2.8 Land**

374
 375 Fig.9 Structure of the *Land* sector. Blue lines indicate connections inside the sector,
 376 red dotted lines indicate connections with other sectors.

377 The *Land* sector simulates the area changes of six land use types (cropland, forest,
 378 grassland, wetland, settlement, and others) based on the land transfer matrix obtained
 379 from historical remote sensing data (Xu et al., 2018). The land transfer matrix calculates
 380 the inflow and outflow of each land category and can be configured to represent the
 381 influence of future land use drivers (Fig. 9). This sector outputs vegetation area
 382 (including forest, grassland, and cropland), which influences the *Water Supply* sector.
 383 Cropland area changes impact the *Food* sector, while land use conversion also plays a
 384 role in the *Carbon* sector.

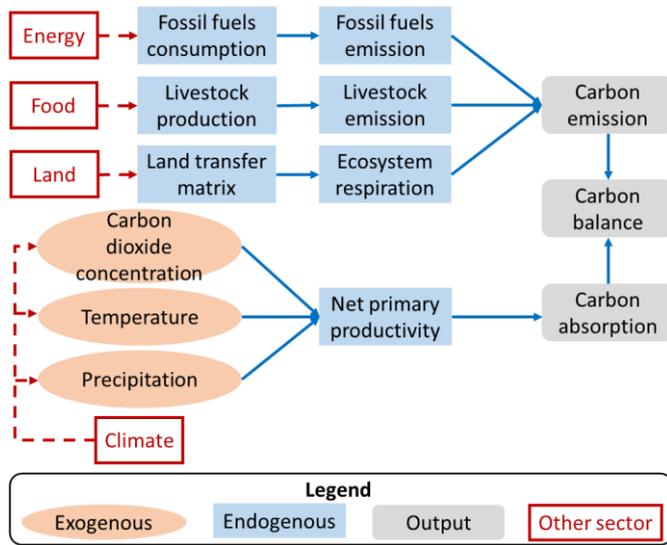

385 Based on the initial land use area ($IniArea_i$), the transfer matrix determines the area

386 ($Area_i$) allocated to each land use type (Equations 11, S60-S66),

387
$$Area_i = IniArea_i + \int (\sum_{i=1}^6 FTM_{i,j} - \sum_{j=1}^6 FTM_{i,j}) dt \quad (11)$$

388 where $FTM_{i,j}$ is the final land use transfer matrix, indicating the area of land use i
 389 transferred to land use j , i and j represent six land use type.

390 **2.2.9 Carbon**

391
 392 Fig.10 Structure of the *Carbon* sector. Blue lines indicate connections inside the
 393 sector, red dotted lines indicate connections with other sectors.

394 The *Carbon* sector simulates the basin’s carbon balance processes, including
 395 carbon emission and absorption, adapted from the carbon cycle of ANEMI (Davies and
 396 Simonovic, 2011). Carbon emissions (CE) encompass fossil fuel emissions, and
 397 livestock emission, and ecosystem respiration, which are influenced by outputs from
 398 the *Energy*, *Food*, and *Land* sectors (Fig. 10).

399 Fossil fuel and livestock emissions are calculated based on fossil fuel consumption,
 400 livestock production, and their respective emission coefficients. Ecosystem emissions
 401 include carbon released from burning as well as from the decomposition of biomass,
 402 litter, humus, and charcoal, which are determined by carbon pools’ lifespans,

425 * Listed are some typical variables of each sector

426 3 Model validation and application

427 3.1 Historical model validation

428

429 Fig.11 Validation of human system processes during historical period of 1981-2020.

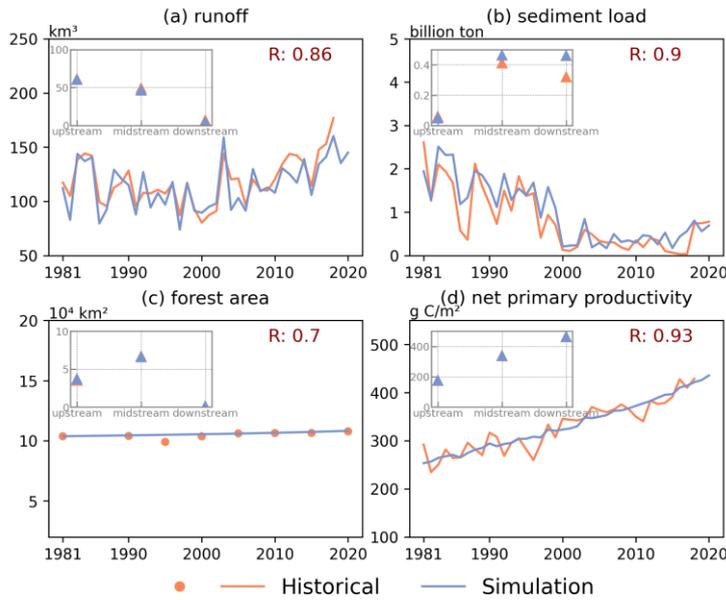

430 (a) total population in *Population* sector; (b) GDP in *Economy* sector; (c) water

431 withdrawal in *Water Demand* sector; (d) electricity generation and (e) coal

432 consumption in *Energy* sector; (f) crop production in *Food* sector. Pink triangles in the
433 upper left sub-image represents the average of historical and simulation value in
434 1981-2020 of each province in the YRB.

435 We compared model performance during the historical period (1981–2020) against
436 historical data. These data are sourced from multiple channels, including statistical
437 yearbooks, hydrological stations, remote sensing observations, and outputs from other
438 models (Table S3).

439 For human sectors, the simulation accuracy of selected key variables from each
440 sector is consistently high ($R > 0.95$), including total population, gross domestic
441 product (GDP), water withdrawal, electricity generation, coal consumption, and crop
442 production across the nine provinces (Fig.11). However, the accuracy varies among
443 provinces, particularly for GDP, electricity generation, coal consumption, and crop
444 production. Some provinces, like Neimeng, exhibit lower simulation accuracy for
445 certain indicators than others, probably due to the simplification of relevant modelled
446 processes, imperfect parameterizations, and external policy interventions. Among all
447 sectors, the greatest uncertainty arises in simulating coal consumption, because the
448 absence of a clear historical trend results in poor fitting performance. Nevertheless, the
449 model performs reasonably well in the human sectors, effectively capturing the
450 historical dynamics of human systems in the YRB.

451

452 Fig.12 Validation of the natural system processes during historical period of 1981-
 453 2020. (a) runoff in *Water Supply* sector; (b) sediment load in *Sediment* sector; (c)
 454 forest area in *Land* sector, and the historical dataset is discontinuous; (d) net primary
 455 productivity in *Carbon* sector. Pink triangles in the upper left sub-image represents
 456 the average of historical and simulation value in 1981-2020 of each sub-basin in the
 457 YRB.

458 For natural sectors, the simulation accuracy for runoff, sediment load, forest area,
 459 and NPP in the YRB is relatively high ($R > 0.7$) (Fig.12). At the sub-basin level, the
 460 overall performance is satisfactory; however, the model shows lower accuracy in
 461 simulating sediment transport in the mid- and downstream. Compared to the human
 462 sectors, the natural sectors generally exhibit lower correlations with historical data,
 463 largely due to the simplifications required when modeling physically complex natural
 464 processes. Nevertheless, the model is still capable of capturing the historical dynamics
 465 of natural processes in the YRB.

466 Sensitivity analyses with randomly generated parameter values reveal growing

467 uncertainty in the long-term trajectories of socio-economic and natural variables; the
 468 model maintains behavioral robustness across all runs without catastrophic collapse or
 469 unrealistic oscillations (see Supporting Information S3 for details).

470 **3.2 Model application for future projection**

471 **3.2.1 Future baseline scenario**

472 The future baseline scenario represents a trajectory in which existing plans and
 473 policies continue to operate without substantial changes in external environments. The
 474 development of the baseline scenario primarily relies on variables from the *Population*,
 475 *Economy*, *Water Demand*, and *Land* sector based on available government planning
 476 documents, historical trends, and other projections (Table 2). For future projections,
 477 variables or parameters not specified in the table are held constant at historical levels
 478 from their most recent year. Future climate data (2015-2100) are from the ensemble
 479 mean of 11 CMIP6 models (ACCESS-CM2, CESM2, CMCC-ESM2, GFDL-ESM4,
 480 INM-CM4-8, INM-CM5-0, IPSL-CM6A-LR, MIROC6, MRI-ESM2-0, UKESM1-0-
 481 LL, and HadGEM-GC31-LL) (available at
 482 <https://cds.climate.copernicus.eu/datasets/projections-cmip6?tab=download>) for the
 483 SSP 2-4.5 because this scenario aligns more closely with the climate trends in the YRB.
 484 To ensure temporal consistency, CMIP6 historical climate data (1981–2014) were used
 485 instead of observed historical records. To reduce systemic biases in the raw CMIP6 data,
 486 we applied bias correction using CN05 and ground weather stations observations from
 487 1981 to 2014. By statistically aligning the mean of the CMIP6 data with observation
 488 records, systemic bias is removed while retaining the temporal consistency required for
 489 long-term simulation.

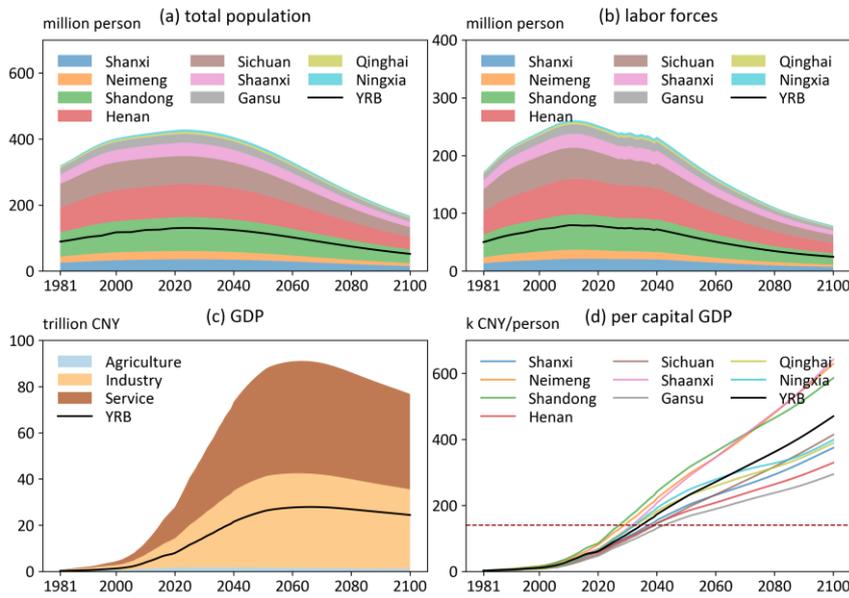

490 We run the model under the future baseline scenario to project the evolution of
 491 CHANS in the basin from 2021 to 2100 (see Supporting Information S6 for details of
 492 future scenario design and supplementary spreadsheet for exogenous variables).

493 Table 2 Settings of key variables in the future baseline scenario

Sector	Variables	Future baseline
--------	-----------	-----------------

Population	• Total fertility	• 2024 United Nations Population Projections
	• Gender ratio	• 2024 United Nations Population Projections
	• Average years of schooling	• The national maximum in 2023 (Germany) as the upper limit
	• Urban and rural population ratio	• Analysis and Forecast of Urbanization Trends in China's Modernization by 2020
	• Labor force	• Delay retirement age
Energy	• Electricity generation sources ratio	• Projected provincial-level energy structure meeting China's carbon peaking and carbon neutrality goals (Li et al., 2024)
	• Irrigation intensity	• Irrigation water use intensity declines linearly (1%/yr) to its minimum value.
Water Demand	• Industry, service, livestock water use intensity	• Industry, service and livestock water use intensity declines linearly (1%/yr) to its minimum value.
Land	• Land use area	• Cropland, forest, and grassland are allowed to be converted into each other, but not to unused land; unused land can be converted to the rest land; wetlands are fixed.
		• Minimum cropland area above the red line for cropland protection.
Climate	• Temperature	• SSP 2-4.5 — CMIP 6
	• Precipitation	
	• Potential evapotranspiration	
	• Precipitation intensity	
	• CO ₂ concentration,	

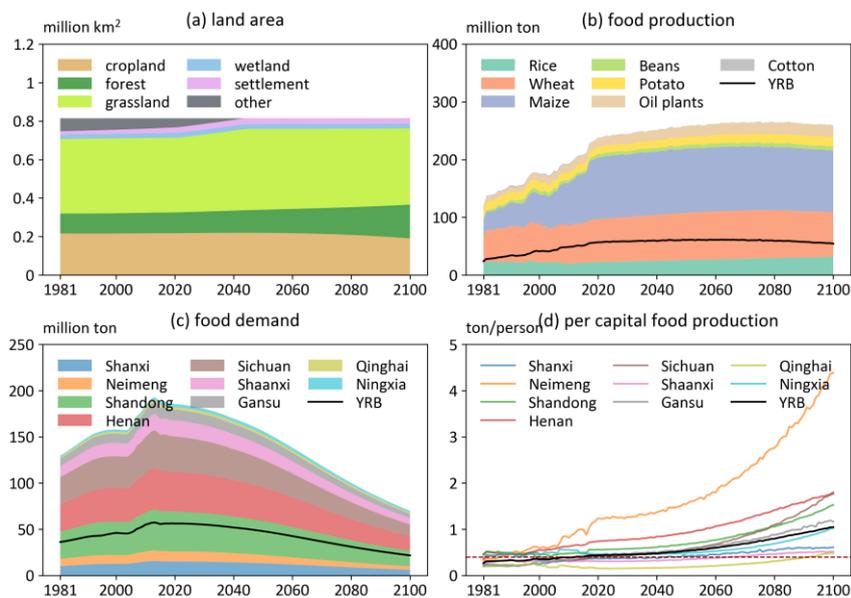

494 **3.2.2 Projection of CHANS dynamics in future baseline scenario**

495
 496 Fig.13 Changes in key variables of the *Population* and *Economy* sector in the future
 497 baseline scenario: (a) the total population, (b) the total labor forces, (c) the gross
 498 output of agriculture, industry, and service, and the total gross domestic output, (d) the
 499 per capita GDP in nine provinces and YRB.

500 The model simulates human and natural system dynamics under the future
 501 baseline scenario and produces outputs for nine provinces and their corresponding areas
 502 within the YRB. The simulation results are reported either at the provincial level (nine
 503 provinces) for human system sectors or at the basin level (basin boundary) for natural
 504 system sectors. The total population in the nine provinces and the YRB is projected to
 505 peak in 2023 and 2024, at 429 million and 131 million, respectively, driven by declining
 506 fertility rates (Fig.13 (a)). The labor force peaks earlier, reaching 261 million in the nine
 507 provinces in 2012 and 79 million in the YRB in 2011 (Fig.13 (b)). After 2025, the labor
 508 force is projected to increase again due to the delayed retirement policy. GDP in the
 509 nine provinces is expected to increase until a peak in 2063, at 91 trillion CNY (three

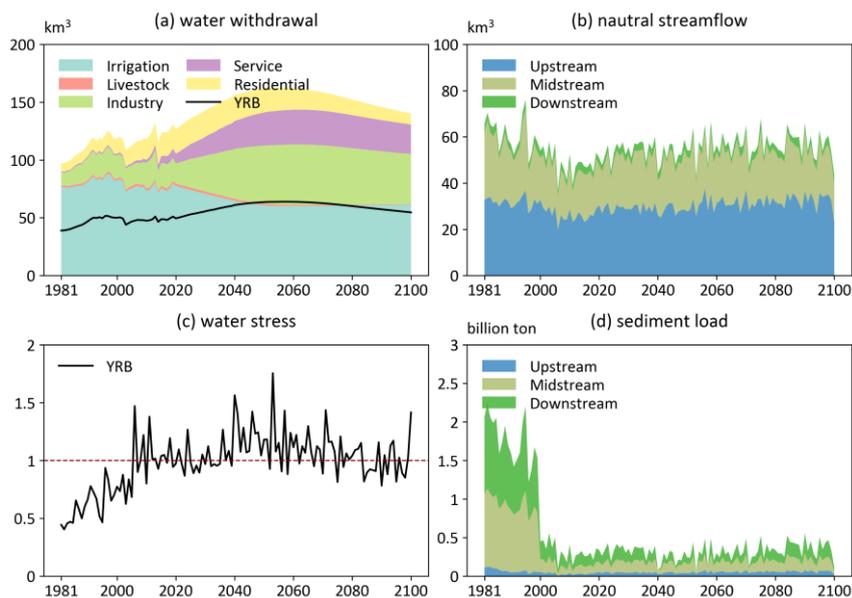

510 times the 2020 level, in 2020 constant prices), under the influence of a labor force
 511 decline, with the YRB reaching its peak four years later (Fig.13 (c)). In contrast to total
 512 GDP, per capita GDP in all regions is projected to continue rising throughout the future
 513 period (Fig.13 (d)). Although all provinces demonstrate improvements in economic
 514 status and living standards, considerable regional disparities persist. Among the nine
 515 provinces, Shaanxi demonstrates the largest growth in average per capita GDP from
 516 2021 to 2100 relative to the historical period (1981-2020), with a more than
 517 seventeenfold increase, while the YRB as a whole shows an over thirteenfold increase.

518
 519 Fig.14 Land and food in the future baseline scenario. (a) land area in the YRB; (b-d)
 520 food production of seven crop types, food demand and per capita food production in
 521 nine provinces and the YRB, red dotted line represents the 0.4 tons international food
 522 security threshold.

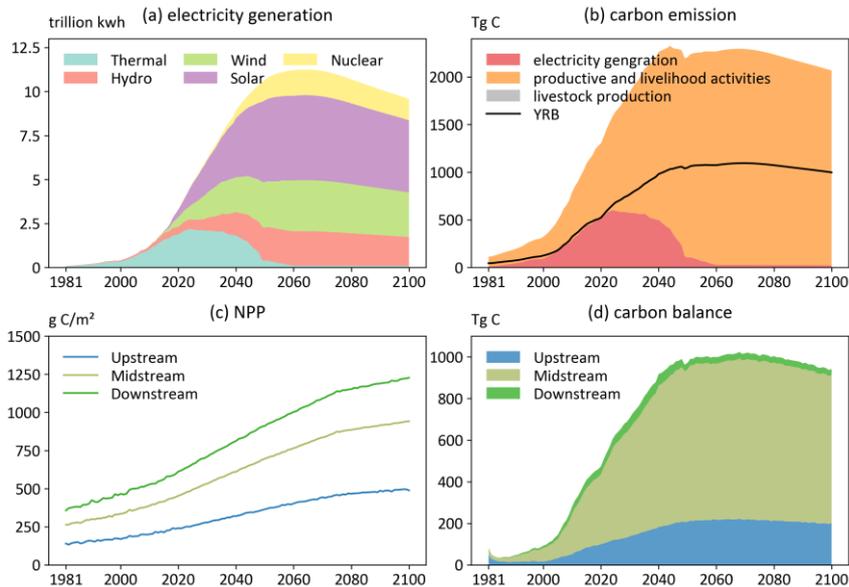

523 Under the future baseline scenario, land use patterns remain relatively stable based
 524 on historical trends (Fig. 14(a)), as no new land use policies are introduced and
 525 cropland area in each province has to stay above the red line (a mandatory minimum

526 ~~cropland area for each province threshold~~ for food security) (Fig.14 (a)). (China's
 527 Cropland Red Line policy). The forest area is projected to increase gradually, reaching
 528 62% above the 2021 level by 2100, while the cropland area is expected continue
 529 declining, falling 12% below the 2021 level. Total crop production in nine provinces
 530 and YRB is projected to peak in 2079 and 2062 (Fig.14 (b)), respectively, driven by the
 531 combined effects of declining cropland area and increasing crop yields. Food demand
 532 in both the nine provinces and the YRB as a whole peaked in 2013 (193 million tons
 533 and 57 million tons, respectively) (Fig.14 (c)), largely driven by population dynamics.
 534 In the future, per capita food production in the YRB is projected to consistently exceed
 535 the international food security threshold of 0.4 tons per person (Fig.14 (d)). However,
 536 in certain years, provinces such as Qinghai and Shaanxi could fall below this standard.

537
 538 Fig.15 Water demand and supply in the future baseline scenario. (a) water withdrawal
 539 across five water-use sectors in nine provinces and the YRB; (b) natural streamflow in
 540 up-, mid- and downstream; (c) water stress in the YRB, red dotted line represents the
 541 water security threshold; (d) sediment load in the up-, mid- and downstream.

542 Total water withdrawal in the nine provinces and the YRB is projected to peak in
543 2056 and 2058, reaching 162 km³ and 64 km³, respectively (Fig.15 (a)). Irrigation water
544 withdrawal is expected to decline, driven by reductions in cropland area and irrigation
545 intensity, the latter resulting from improvements in irrigation efficiency assumed in the
546 scenario. Peaks in residential, industrial, service, and livestock water withdrawals are
547 primarily associated with projected peaks in population and GDP. Natural streamflow
548 is projected to exhibit a fluctuating upward trend of 0.073 km³/year basin-wide (Fig.
549 15(b)), with the most significant growth in the upstream region (0.068 km³/year).
550 Considering the ecological flow requirement of 18.7 km³ (YRCCMWR, 2015), water
551 stress (calculated as water consumption divided by (natural discharge - ecological flow))
552 is expected to decline in the latter half of the century, largely due to the peak and
553 subsequent reduction in water withdrawal. However, overall water stress is projected
554 to exceed historical levels in 2041 and will fall below 1 in 38% of the years (Fig.15 (c)),
555 reflecting persistent human–water tensions and future trade-offs between ecological
556 and human water use. As a result of reduced actual streamflow, sediment transport in
557 the Yellow River is projected to decline sharply (Fig.15 (d)), with a 71% decrease in
558 sediment load relative to the historical period.

559 Fig.16 Electricity and carbon in the future baseline scenario. (a) the electricity
 560 generation from five sources in nine provinces; (b) carbon emission from three
 561 sources in nine provinces and the YRB; (c-d) the net primary productivity and carbon
 562 balance in the up-, mid-, and downstream.
 563

564 Since the energy system is transitioning to carbon neutrality goals under the future
 565 baseline scenario, thermal power generation is projected to decline sharply, while clean
 566 energy (hydropower, wind, solar, and nuclear) will become the dominant source for
 567 electricity generation (Fig.16 (a)). The large-scale adoption of clean energy will lead to
 568 a peak in carbon emissions from electricity generation in 2024 (Fig.16 (b)). In contrast,
 569 emissions from productive and livelihood activities are projected to rise substantially
 570 over time, with total human emissions in the YRB reaching a peak in 2044. NPP is
 571 anticipated to increase markedly in response to CO₂ concentration increase (Fig.16 (c)).
 572 Although the carbon balance of the YRB has remained positive (net carbon source), it
 573 is expected to gradually decline after 2068 (Fig.16 (d)), indicating that the basin's
 574 ecosystems alone cannot fully offset human-induced carbon emissions.

575 The above projections of future baseline scenarios highlight persistent challenges

576 to achieving sustainable development in the YRB, underscoring the need for integrated
577 policy responses to address these challenges. Priority should be given to enhancing
578 water-use efficiency and establishing adaptive water resource allocation mechanisms
579 that balance ecological and human water needs. Sediment management strategies,
580 which combine ecological restoration with hydraulic regulation, are necessary to
581 maintain river stability and delta health. To counter the decline in labor force, policies
582 should promote industrial upgrading and technological innovation. Strengthening the
583 basin's carbon mitigation capacity requires accelerating the clean energy transition and
584 expanding ecological restoration to enhance carbon sequestration. Finally, a multi-
585 sectoral, CHANS-based governance framework should be established to coordinate
586 water, land, energy, and carbon management, enabling evidence-based scenario
587 analysis and adaptive policy design for long-term sustainability.

588 **4 Discussion and conclusions**

589 The development of the CHANS-SD-YRB model involves a series of key
590 considerations in translating a conceptual framework into a functioning model. The
591 framework focuses on human–water interactions in the YRB, integrating bidirectional
592 feedback between human and natural processes. SD was chosen to implement the
593 framework, as it effectively captures feedback, non-linear relationships, and cross-
594 sectoral linkages within complex human–natural systems, while remaining practical
595 and straightforward to use. For quantitative representation of human–natural processes,
596 we prefer theoretical methods that incorporate key interactions within the system
597 suitable for implementation using SD. For example, the Budyko framework connects
598 the *Land*, *Climate*, *Water Demand*, and *Water Supply* sectors. Relative to distributed
599 hydrological models, it offers lower computational complexity and reduced data
600 requirements. The Cobb–Douglas production function links the *Population* and
601 *Economy* sectors. Compared with Computable General Equilibrium models (Fujimori
602 et al., 2014a), it is simpler to construct and requires fewer parameters and data inputs.
603 When no suitable theoretical framework/method is available to describe a process, we

604 rely on empirical relationships derived from historical data. For example, crop yields
605 are estimated using fitted relationships between climate variables, fertilizer application,
606 and historical yields. For processes that cannot be represented through empirical
607 functions, we apply literature-based estimates to obtain approximate quantitative
608 relationships, such as fossil fuel emission factors. For processes influenced by external
609 drivers that cannot be endogenously expressed within the model, we quantify them
610 using exogenous parameters derived from historical statistics, such as water intensity.
611 Given the heterogeneous human–natural interactions in the YRB, we represent all
612 processes at the provincial and sub-basin scales using scale-specific parameters, except
613 where parameters or data at these levels are unavailable.

614 The CHANS-SD-YRB model explicitly couples multiple human and natural
615 sectors, enabling a more integrated representation of feedbacks across population,
616 economy, energy, food, water, sediment, land, carbon, and climate. Unlike models that
617 focus on specific sectors or isolated subsystems—such as eco-hydrological models and
618 sediment transport models, which may well capture individual processes but cannot
619 represent the complex human–nature interactions driving system dynamics. Our
620 model’s integration of human and natural sectors provides a robust framework for
621 addressing regional CHANS challenges and offers practical guidance for sustainable
622 development. The CHANS-SD-YRB model serves as a comprehensive platform for
623 conducting system dynamics prediction, scenario analysis, policy evaluation, and
624 optimization, to alleviate human–water conflicts, ensure food security, and achieve
625 long-term sustainability. For example, analysis of the impacts of the 1987 Yellow River
626 water allocation policy (Song et al., 2024) offer valuable insights for adjusting
627 interprovincial water distribution to promote sustainable water governance; assessment
628 of ecological restoration policies (Li et al., 2015) can guide future ecological
629 engineering; spatiotemporal dynamics of future water gaps can serve as a valuable
630 reference for planning inter-basin water transfers. The model’s flexibility also allows
631 for the incorporation of additional feedback, for example, linking water scarcity to

632 industrial output or climate warming to agricultural productivity. These could include
633 the effects of global warming on human health (Yin et al., 2023a) and economic
634 activities (Nordhaus, 2017), water constraints on production, dietary shifts influencing
635 carbon emissions and land use (Ren et al., 2023), and the trade-offs between carbon
636 mitigation and food security (Xu et al., 2022).

637 Nevertheless, the model remains subject to further refinement. The current
638 simplifications of natural processes could be replaced with more sophisticated models
639 to enhance simulation accuracy. For instance, the YRB hydrological processes involve
640 highly complex human interventions, including reservoir, conservation, and
641 revegetation projects (Wang et al., 2025). The refined runoff simulations by distributed
642 hydrological models improve water supply assessments through their better
643 characterization of spatial heterogeneity in soil, precipitation, and snowmelt (Cong et
644 al., 2009). For human processes, the *Energy* and *Economy* sectors could be refined to
645 model more detailed industry subsectors and emerging trends in energy demand driven
646 by electrification. Given the uncertainty in future climate change, the sensitivity of the
647 system's future projections to alternative climate change scenarios (SSP1-2.6, SSP3-
648 7.0, or SSP5-8.5) warrants exploration. Moreover, there are still important feedbacks
649 absent from the current coupling framework. Notable examples include the effects of
650 land use change on climate, the effects of climate change on economic growth, and the
651 effects of pricing on energy use and carbon emissions. These missing feedbacks could
652 be incorporated based on recent studies, including the land use feedback on
653 precipitation through moisture recycling (Sang et al., 2025a), socioeconomic losses
654 from impacts of climate change and extremes (Waidelich et al., 2024b), and integration
655 with Computable General Equilibrium (CGE) models (Fujimori et al., 2014b). In
656 particular, recent modeling work by Wells et al. (2026) demonstrated that a more
657 comprehensive representation of climate-to-society feedbacks is possible within the
658 system dynamics framework. Additionally, the model's spatial and temporal resolutions
659 are relatively coarse due to the inherent mismatch in spatiotemporal scales between

660 human and natural processes. The scale at which we make the model represents a
661 practical compromise, constrained by data availability and aligned with the study's
662 objectives. Simulations at finer scales (e.g., monthly, daily, or gridded) would enhance
663 the representation of natural processes (e.g., hydrological processes, land use changes,
664 and food production) and the associated spatiotemporal heterogeneity (e.g., daily
665 simulations can assess the impacts of extreme weather). However, it may also
666 exacerbate the scale mismatch with socioeconomic processes, making it challenging to
667 analyze cross-sectoral dynamics. Technically, the inherent limitations of the SD
668 software restrict the model's ability to represent temporal fluctuations and spatial
669 variations. To overcome this, transitioning from the VENSIM platform to a code-based
670 implementation will be necessary, which would also facilitate coupling with other
671 models. Future research should prioritize these improvements to strengthen both the
672 performance and applicability of the model.

673 Drawing on the conceptual framework of Sang et al. (2025), this study implements
674 it into a fully functional, validated System Dynamics model tool, CHANS-SD-YRB 1.0.
675 The model fills the gap in CHANS modeling for the YRB. It integrates the dynamics
676 of ten interconnected sectors: *Population, Economy, Energy, Food, Water Demand,*
677 *Water Supply, Sand, Land, Carbon, and Climate*, achieving reciprocal feedback
678 between human and natural systems. This model can serve as a robust tool to inform
679 policy decisions that influence the evolution of coupled human–natural systems and to
680 explore pathways for optimizing these systems toward sustainability. Furthermore, the
681 modeling process provides valuable experience for regional CHANS modeling and
682 contributes to advancing the broader development of CHANS models at the regional
683 scale.

684 **Code and data availability**

685 The CHANS-SD-YRB V1.0 model (Vensim DSS format), along with the input
686 data and simulation outputs used in this study, are openly accessible at

688 https://github.com/sangshan-ss/CHANS_SD_YRB.

689 **Author contributions**

690 Conceptualization: YL, SS¹, BF. Data curation: SS¹. Formal analysis: SS¹.
691 Funding acquisition: BF, YL. Investigation: YL, SS¹. Methodology: SS¹, YL, BF.
692 Project administration: YL. Resources: YL. Software: SS¹, SZ, LY. Supervision: YL,
693 BF. Validation: SS¹, SZ, LY. Visualization: SS¹. Writing – original draft: SS¹. Writing –
694 review and editing: SS¹, YL, SW, YXL, XTW, SS², WZ, XHW. (Note: SS¹ refers to
695 Shan Sang, and SS² refers to Shuang Song, to distinguish between authors with identical
696 initials.)

697 **Competing interests**

698 The authors declare that they have no conflict of interest.

699 **Acknowledgements**

700 We thank Dr. Weishuang Qu for developing the Threshold 21 model in the
701 Millennium Institute that inspired this study, and also for his and Dr. Haiyan Jiang's
702 generous help with the CHANS-SD-YRB modeling. We also thank the data support
703 from Dr. Xianghui Kong, and National Earth System Science Data Center, National
704 Science & Technology Infrastructure of China (<http://www.geodata.cn>).

705 **Financial support**

706 This study is supported by the National Natural Science Foundation of China
707 (Grant No. 42041007), and the Fundamental Research Funds for the Central
708 Universities.
