## Abstract.

Ammonia ( $\text{NH}_3$ ) is a key atmospheric precursor of fine particulate matter and a marker of agricultural and biomass burning emissions. In Central America,  $\text{NH}_3$  variability remains largely unquantified. This study presents the first integrated spatiotemporal assessment of atmospheric  $\text{NH}_3$  over Guatemala (2015–2023) using multi-satellite observations (IASI A/B/C), combined with MODIS fire data, Sentinel-2 land cover, ERA5 meteorology, and CAMS reanalysis. Annual median  $\text{NH}_3$  columns remained relatively stable, reflecting persistent agricultural sources dominated by fertilizer use and livestock. Significant anomalies occurred in 2016, 2020, and 2023, with 2020 showing the highest annual and monthly  $\text{NH}_3$  levels. Seasonal peaks in April–May coincided with the regional fire season, followed by a sharp decline after rainfall onset. Hotspots were consistently detected in northern (Petén–Quiché) and southern (Escuintla) agricultural regions. The most extreme episode in April 2020 recorded 957 active fires over  $\sim 1,486 \text{ km}^2$ , largely within the Maya Biosphere Reserve. Elevated temperature ( $+0.3 \text{ }^\circ\text{C}$  above the 2015–2023 mean) and high precipitation ( $+17\%$  above average) favored  $\text{NH}_3$  accumulation despite reduced anthropogenic activity during the COVID-19 lockdown. These results indicate that Guatemala's  $\text{NH}_3$  variability is shaped by a stable agricultural baseline with superimposed fire-driven peaks, modulated by climatic anomalies. Continuous satellite monitoring is essential to improve emission inventories and support strategies to reduce biomass burning impacts across Central America.

## 1 Introduction

Atmospheric ammonia ( $\text{NH}_3$ ) utilizes a considerable influence on air quality and ecological integrity through its potential for long-range transport and interaction with prevailing meteorological conditions (Zhou et al., 2019). As a reactive nitrogen (Nr) compound,  $\text{NH}_3$  plays a fundamental role in the global nitrogen cycle and a variety of biogeochemical processes, representing a dominant form of nitrogen present in terrestrial and atmospheric systems (Sutton et al., 2007, 2013; Whitburn et al., 2016b). Despite its relatively short atmospheric lifetime ranging from several hours to a few days due to its high deposition efficiency

and conversion into particulate ammonium, current surface-based monitoring approaches remain inadequate for providing accurate global emission estimates, often introducing substantial uncertainties (Dammers et al., 2016; Herrera et al., 2022).  $\text{NH}_3$  is also a key component in atmospheric chemistry and in the coupling of nitrogen and carbon cycles within ecosystems, with broad consequences regarding climate regulation, agricultural sustainability, air quality and public health.  $\text{NH}_3$  emissions originate from both natural and anthropogenic activities, with the latter contributing the majority of the global  $\text{NH}_3$  burden. The agricultural sector remains the principal source, accounting for over 81% of total anthropogenic emissions globally (Van Damme et al., 2021; Wyer et al., 2022), while additional anthropogenic contributions stem from residential combustion, vehicular exhaust, industrial production, and wastewater treatment systems (Abeed et al., 2022; Dragosits et al., 2002; Sutton et al., 2007).

Although agriculture particularly through the use of fertilizers and manure remains the dominant source of atmospheric  $\text{NH}_3$ , recent studies suggest that emissions from non-agricultural sources, particularly those associated with vehicular traffic, may be significantly underestimated (Chen et al., 2024; Chen and Wang, 2025; Farren et al., 2020; Gu et al., 2023; Zhou et al., 2017). Empirical evidence indicates that diesel vehicles equipped with selective catalytic reduction (SCR) systems can emit  $\text{NH}_3$  as an unintended byproduct (Sun et al., 2017; Wen et al., 2023). Vehicular  $\text{NH}_3$  emissions are known to contribute to the rapid formation of fine particulate matter, particularly during air pollution episodes, underscoring the predominant role of fossil fuel combustion as a non-agricultural  $\text{NH}_3$  source in urban environments (Farren et al., 2020, 2021; Pan et al., 2016). Additionally, various industrial activities including steel production (Chen and Wang, 2025), power generation, and fertilizer manufacturing also release substantial amounts of  $\text{NH}_3$  into the atmosphere (Van Damme et al., 2018; Gu et al., 2023).

In recent decades, satellite remote sensing has significantly advanced the detection of atmospheric  $\text{NH}_3$ , leading to the development of several global  $\text{NH}_3$  emission datasets, notably from the Infrared Atmospheric Sounding Interferometers (IASI) instrument. For this study, we also include fire-based emission datasets such as the Global Fire Emissions Database (Giglio et al., 2006, 2013; van der Werf et al., 2010, 2017), the Global Fire Assimilation System (Remy and Kaiser, 2014) developed by the European Centre for Medium-Range Weather Forecasts (ECMWF), and two fire products from the National Aeronautics and Space Administration (NASA), based on fire radiative power (FRP) measurements (Fu et al., 2020; Li et al., 2020; Remy and Kaiser, 2014; Vermote et al., 2009; Wooster et al., 2003).

Central America's climate is significantly shaped by the two oceans it borders, with the vast Pacific Ocean, spanning nearly half the Earth's circumference at the equator, being especially crucial for climate regulation by El Niño brings drier conditions to Guatemala, while La Niña produces more precipitation (Bardales Espinoza et al., 2019) Guatemala's geomorphological attributes and geospatial coordinates inherently facilitate a multitude of microclimatic zones and pronounced climatic heterogeneity, the variability has been amplified in recent years by the nation's persistent susceptibility to extreme meteorological phenomena, including prolonged arid periods and intense tropical cyclones, both of which are intensified by

65 the overarching impacts of anthropogenic climate change (Alfaro Marroquín and Gómez, 2019). Guatemala's climate deviates from the typical four-season delineation observed in the Northern Hemisphere. Instead, it is characterized by two distinct periods: the wet season, spanning from May to October, and the dry season, occurring from November to April (INSIVUMEH, 2018; Orrego León et al., 2021).

70 Furthermore, these climate condition directly influence and intensify of biomass burning events, particularly during dry season, Guatemala is exposed to a variety of threats, with wild-fires being one of the main threats in recent decades (CONRED, 2025). Guatemala has experienced increasing concern from fire-related activities that are strongly tied to agricultural expansion, shifting cultivation, and deforestation. These practices, often used to clear land for crops or grazing, are typically intensified during the dry months, aligning with peak fire activity (Liu et al., 2024; Monzón-Alvarado et al., 2012). Guatemala consistently  
 75 reports a high number of fire hotspots (CONRED, 2025), especially in years dominated by El Niño-induced drought conditions (Chuvieco et al., 2019; CONRED, 2025; Giglio et al., 2013). The recurrence of such fires in forested and agro-pastoral zones not only transforms land cover but also releases large quantities of reactive trace gases and aerosols, including atmospheric  $\text{NH}_3$  into the atmosphere (Andreae, 2019; Pohl et al., 2022; Wyer et al., 2022). Despite this, the role of biomass burning as a driver of  $\text{NH}_3$  emissions remains underexamined in Central American air quality studies.

80 Despite the increasing availability of satellite-based datasets for monitoring atmospheric  $\text{NH}_3$  there remains a significant lack of regional-scale studies in Central America, particularly in Guatemala, where land use dynamics and biomass burning are likely to contribute substantially to  $\text{NH}_3$  emissions. Previous research has often overlooked the integrated role of multiple environmental drivers such as meteorological variability, and land cover change. This study investigates the monthly  
 85 spatiotemporal dynamics of atmospheric  $\text{NH}_3$  emissions in Guatemala from 2015 to 2023, using three satellite observations from IASI onboard of the Meteorological Operational satellite programme (MetOp), MetOp-A, MetOp-B, and MetOp-C, in combination with land cover classification from the Environmental Systems Research Institute (ESRI), ERA5 meteorological data, and fire activity from MODIS. The research aims to identify hotspots and the interannual and seasonal  $\text{NH}_3$  emission variability. In addition, this study employed spatial clustering using k-means algorithm to partition  $\text{NH}_3$  emission patterns and  
 90 explore their heterogeneity, with a particular focus on land cover types and the influence of fire-pixel activity. To ensure the reliability of the fire data, fire-pixels from MODIS with a confidence level  $>70\%$  were included in the analysis. A case study in 2020 further examines peak emission conditions in relation to extreme fire events linked to agriculture and meteorological anomalies. The result of this study provides critical insight for a region where such integrated analyses remain scarce.

## 2 Methodology

### 2.1 Data analysis

This section presents a comprehensive analysis of atmospheric ammonia ( $\text{NH}_3$ ) concentrations and related environmental factors in Guatemala from 2015 to 2023, utilizing concatenated IASI A/B/C sensor data, incorporating both morning and night observations for enhanced representativeness. We first detail the spatiotemporal variability of  $\text{NH}_3$  emissions, examining annual trends that reveal generally the baseline with notable outliers and a potential recent increase. Seasonal patterns are also explored, highlighting a distinct annual cycle with a pronounced peak during the months of April and May. Spatially, elevated  $\text{NH}_3$  emissions are consistently observed in the northern and southern regions where cropland is dominated, contrasting with lower rates in the central midlands, a pattern further elucidated by k-means cluster analysis which categorizes regions by emission intensity. Utilizing these IASI observations, specific  $\text{NH}_3$  source regions within Guatemala have been identified and characterized, revealing that the majority of these elevated emission zones are primarily associated with agricultural practices (e.g., farming and spreading activities) and, in some northern areas, a combination of rangeland and built-up development.

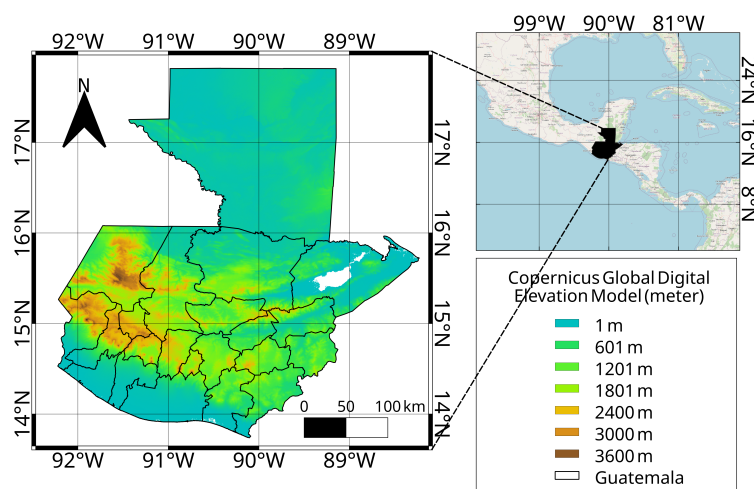

Subsequently, the interrelationships between  $\text{NH}_3$ , other air pollutants (nitrogen dioxide [ $\text{NO}_2$ ] and sulfur dioxide [ $\text{SO}_2$ ]), fire activity, and key meteorological variables (temperature, relative humidity, boundary layer height, surface pressure, and total precipitation) are explored through Pearson correlation analysis. This investigation reveals significant associations, such as strong positive correlations between  $\text{NH}_3$  and both  $\text{NO}_2$  and fire activity, alongside inverse relationships with parameters like relative humidity. Finally, a case study of the April 2020  $\text{NH}_3$  anomaly is presented. This period is particularly noteworthy for recording the highest emission levels during the study, coinciding with specific meteorological conditions, fire activity, and the COVID-19 lockdown period. This detailed examination integrates spatial distribution maps, wind patterns, and vertical profiles to provide deeper insights into the potential drivers and atmospheric dynamics contributing to this significant  $\text{NH}_3$  event.

### 2.2 Study location

This study focuses on the Republic of Guatemala, a Central American country situated between latitudes  $13.5^\circ\text{N}$  to  $17.8^\circ\text{N}$  and longitudes  $88.2^\circ\text{W}$  to  $92.2^\circ\text{W}$ . Guatemala encompasses a diverse range of ecological regions, topographical variations, and land use patterns, all of which have significant implications for atmospheric  $\text{NH}_3$  dynamics. The country is characterized by a complex zone of agricultural lands, forested highlands, volcanic zones, and rapidly urbanizing areas factors that contribute to both natural and anthropogenic  $\text{NH}_3$  emissions. Agriculture remains a cornerstone of the Guatemalan economy and landscape, with extensive cultivation of crops such as maize, bean, coffee, sugarcane, oil palm, and bananas (FAO, 2019; Hervas, 2019; Lopez-Ridaura et al., 2019). Fertilizer application and livestock farming are particularly prevalent in rural regions, making the agricultural sector a dominant source of  $\text{NH}_3$  emissions nationwide. Meanwhile, increasing urbanization

and industrialization, especially around Guatemala City and its metropolitan zone, have introduced additional non-agricultural emission sources, such as vehicular exhaust, industrial activity, and waste treatment processes. Moreover, Guatemala experiences a pronounced dry season (typically November to April) and rainy season (May to October) (Alfaro Marroquín and Gómez, 2019; Bardales Espinoza et al., 2019; INSIVUMEH, 2018; Orrego León et al., 2021), which strongly modulate fire activity, atmospheric transport conditions, and deposition processes relevant to  $\text{NH}_3$  dispersion. Frequent wildfires, especially in the Petén department (northern area of Guatemala) and central highlands during the dry season, contribute further to the atmospheric burden of reactive nitrogen species. The height of Guatemala varies from sea level to 3,000 m above sea level (a.s.l.) in the central plateau and with volcanic peaks that reach 4,200 m a.s.l. (IGM, 2002). Figure 1 shows the digital elevation model (DEM) of the topographic surface in meter over Guatemala using the European Space Agency, 2024). These topographic elevation and environmental anthropogenic conditions make Guatemala an important, yet understudied, region for evaluating  $\text{NH}_3$  variability and its interaction with land cover, climate, and pollution.

### 2.3 ESRI land cover class map

The ESRI Land Use Land Cover (LULC) 2020 dataset was released in June 2021 by the Environmental Systems Research Institute (ESRI) was developed using deep learning models trained on more than 5 billion manually labeled pixel samples derived from Sentinel-2 satellite imagery (Karra et al., 2021). According to (ESRI, 2021) these training samples were collected from 24,000 image tiles globally, each measuring  $510 \times 510$  pixels, and reflect a wide range of land surface types. The LULC 2020-ESRI dataset, based on data from the European Space Agency's Sentinel 2 mission with 10 m spatial resolution, enables

land cover mapping at both national and local scales. The LULC 2020 map is classified into nine classes: Water, Trees, Flooded vegetation, Crops, Built area, Bare ground, Snow/Ice, Clouds, and Rangeland (Karra et al., 2021).

## 2.4 Ammonia (NH<sub>3</sub>) observation from IASI

- 150 Atmospheric total column measurements of NH<sub>3</sub> were obtained from the Infrared Atmospheric Sounding Interferometer (IASI), an instrument onboard of the MetOp A/B/C satellites launched in 2006, 2012, and 2018, respectively (Clarisse et al., 2009, 2019; Coheur et al., 2009). IASI works with a cross-track scanning swath approximately 2200 km wide and provides measurements with a nadir pixel diameter of about 12 km. Positioned aboard sun-synchronous polar-orbiting satellites, the instrument enables near-global coverage twice daily during both daytime and nighttime corresponding to local solar overpass
- 155 times of approximately 09:30 and 21:30, respectively (Clarisse et al., 2010; Van Damme et al., 2017; Whitburn et al., 2017). The vertical sensitivity of NH<sub>3</sub> retrievals is primarily concentrated within the boundary layer, where atmospheric ammonia is most abundant, and is strongly modulated by the thermal difference between the Earth's surface and the overlying atmospheric layers (Clarisse et al., 2009; Whitburn et al., 2016a).
- 160 This study employed version 4 of the ANNI-NH<sub>3</sub> retrieval product (Clarisse et al., 2023), derived from IASI Metop-A/B/C morning and night overpasses for the period 2015–2023, and regridded to a  $0.25^\circ \times 0.25^\circ$  spatial resolution. A major enhancement in this version is the incorporation of the vertical column averaging kernel (AK), which is essential for aligning satellite retrievals with chemistry-transport model simulations by mitigating the influence of the priori NH<sub>3</sub> vertical profiles applied during retrieval. While spatial patterns remain consistent with previous versions, total column values are approximately
- 165 15–20% higher due to improvements in the high-resolution infrared retrieval configuration (HRI), version 4 offers improved uncertainty characterization and enhanced temporal uniformity of the dataset from 2007 to 2023 (Clarisse et al., 2023). The retrieval algorithm estimates a hyperspectral range index from IASI spectra and converts it into NH<sub>3</sub> total column densities using an artificial neural network (Van Damme et al., 2021; Franco et al., 2018; Whitburn et al., 2017).
- 170 This process is supported by consistent ERA5 meteorological reanalysis data, making the product suitable for assessing interannual variability and long-term trends (Hersbach et al., 2020). The instrument's detection limit, which depends on atmospheric conditions such as thermal contrast and NH<sub>3</sub> abundance, is estimated to be as low as  $4\text{--}6 \times 10^{15}$  molecules cm<sup>-2</sup> (Clarisse et al., 2009). The ANNI- NH<sub>3</sub> product has been validated against in situ observations, showing strong regional correlations (Van Damme et al., 2021, 2022; Guo et al., 2012), and has been widely applied in both global (Evangelidou et al.,
- 175 2021) and regional NH<sub>3</sub> emission studies (Chen et al., 2023; Marais et al., 2021a, b).

The NH<sub>3</sub> vertical profiles were obtained from the ECMWF, Atmospheric Composition Reanalysis 4 (EAC4), produced by the Copernicus Atmosphere Monitoring Service (CAMS). The vertical resolution of NH<sub>3</sub> in the model is defined by 60 hybrid sigma-pressure levels, which provide a detailed representation of the atmospheric structure, particularly near the surface where

180 most emissions occur (Inness et al., 2019). These reanalysis datasets incorporate satellite observations and model simulations to provide globally consistent, spatially and temporally resolved atmospheric composition data (Flemming et al., 2017; Inness et al., 2019).

To identify spatial patterns in atmospheric NH<sub>3</sub> emissions and associated land cover characteristics, an unsupervised clustering approach was applied. Clustering is a type of unsupervised machine learning that groups large datasets based on their similarity, allowing for more manageable and interpretable analyses (Ahmad and Dey, 2007; Pham et al., 2005). This analytical approach is particularly beneficial when there is limited or no prior knowledge about the underlying structure of the data (Gašparović et al., 2019). Among clustering methods, the k-means algorithm is one of the most commonly applied and reliable techniques. It partitions data into a predefined number of  $k$  clusters by iteratively determining central points, or centroids, for each group (Pham et al., 2005). The algorithm requires the number of clusters to be specified in advance (Ahmad and Dey, 2007; Mahata et al., 2020). K-means operates using the squared Euclidean distance as its primary metric (Spencer, 2013), which quantifies the separation between two points within a Euclidean space of any dimension (Li et al., 2022). The Euclidean distance between two points,  $p$  and  $q$ , in a  $j$ -dimensional space is mathematically expressed as  $d(p, q)$ .

$$195 \quad d(p, q) = \sqrt{(p_1 - q_1)^2 + (p_2 - q_2)^2 + \dots + (p_j - q_j)^2} \quad (1)$$

The k-means algorithm divides a dataset into  $k$  clusters by aiming to minimize the variance within each group (Li et al., 2022). It operates on a set of input samples  $X = \{x^1, \dots, x^n\}$ , where each  $x^m = \{x_1^m, x_2^m, \dots, x_j^m\}$  represents an observation composed of  $j$  variables, and  $m \in X = \{1, \dots, n\}$ , with  $n$  being the total number of observations. These samples are categorized into  $k$  clusters ( $S_1, S_2, \dots, S_k$ ) with the goal of minimizing the total intra-cluster variance ( $S_{i=1, \dots, k}$ ), as described in Equation (2):

$$200 \quad \underset{S}{\operatorname{argmin}} \sum_{i=1}^k \sum_{X \in S_i} \|X - \mu_i\|^2 \quad (2)$$

The notation  $\|X - \mu_i\|$  represents the squared Euclidean distance between each data point ( $X$ ) and its assigned cluster centroid  $\mu_i$  within a multidimensional Euclidean space (Li et al., 2022). In this research, k-means clustering was utilized to examine the spatiotemporal patterns of NH<sub>3</sub> emissions throughout the specified timeframe (Anne Fouilloux, 2018; Pedregosa et al., 2011). To determine the most suitable number of clusters ( $k$ ), the elbow method was employed (Umargono et al., 2019). This approach assesses the Cluster Sum of Squares (CSS) to identify the point at which the inclusion of additional clusters no longer significantly improves the model performance.

## 210 2.5 Meteorological data from ERA-5

Meteorological variables used in this study were obtained from the fifth-generation global reanalysis (ERA5) (Soci et al., 2024) dataset provided by ECMWF, (Hersbach et al., 2020). Originally available at a horizontal resolution of approximately 31 km, the data were resampled to a  $0.25^\circ \times 0.25^\circ$  grid and both spatially and temporally interpolated to match the IASI NH<sub>3</sub> observation times and locations. The selected meteorological parameters include 2 m air temperature (t2m), 10 m wind speed  
 215 (ws), boundary layer height (blh), relative humidity (derived using 2 m air temperature and dew point temperature), surface pressure (sp), and total precipitation (tp). Correlation analyses between these variables and atmospheric NH<sub>3</sub> concentrations were performed to better understand the meteorological drivers influencing NH<sub>3</sub> variability across Guatemala.

## 2.6 Fires and burned areas

Detected active fires for this work were sourced from the MODIS-Aqua/Terra Thermal Anomalies/Fire locations at 1 km  
 220 FIRMS Near Real-Time (NRT) - Collection 6.1 (Giglio et al., 2021a). This product is processed by NASA's Land, Atmosphere Near real-time Capability for EOS (LANCE) Fire Information for Resource Management System (FIRMS), utilizing swath products (MOD14/MYD14). The thermal anomalies, or active fires, pinpoint the center of a 1 km pixel identified by the MODIS MOD14/MYD14 Fire and Thermal Anomalies algorithm (Giglio et al., 2003, 2006; Justice et al., 2010) as containing one or more fires within that pixel. While monitored at a  $1 \times 1 \text{ km}^2$  resolution, the system is capable of detecting fires as small  
 225 as  $100 \text{ m}^2$ . Furthermore, MODIS captures data by scanning across the Earth's surface about every 1.48 seconds (Giglio et al., 2016).

This scanning mechanism produces 10 image lines in the along-track dimension, with each line capturing 1354 pixels in the along-scan dimension (Wolfe et al., 2002). For every detected fire pixel in this product, three key pieces of information are  
 230 provided: fire location, fire detection confidence, and Fire Radiative Power (FRP) (Giglio et al., 2013). The fire location is defined by the central longitude and latitude of the pixel. Fire detection confidence assesses the probability of a pixel genuinely containing a fire and is categorized as low level: 0% to < 30%, nominal level: 30% to < 80%, high level: 80% to 100% (Giglio et al., 2016, 2021b, a; Hantson et al., 2013). However, several studies recommended using MODIS fire for nominal–high confidence to reduce the number of false alarms (Giglio et al., 2021b, a). Therefore, the study used fire detections with a  
 235 nominal confidence level i.e., >70%. In addition, FRP, which quantifies the energy release rate from the fire (Wooster et al., 2003), was used as a filtering criterion to highlight the most significant fire hotspots. Only pixels with FRP values greater than 40 MW were considered in the analysis, ensuring that the dataset emphasized large and energetically relevant fire events rather than for a small scale or low intensity detections. FRP, which quantifies the energy release rate from the fire, according to the methodology proposed by (Wooster et al., 2003):

240

$$FRP = \frac{\sigma \times A_{\text{pixel}}}{\alpha \times \tau_4} (L_4 - L_{4b}) \text{ (Megawatt: MW)} \quad (2)$$

$A_{pixel}$  is the fire pixel area  $\sigma = 5.6704 \times 10^{-8} \text{ Wm}^{-2} \text{ K}^{-4}$  is the Stefan–Boltzmann constant,  $\alpha = 3.0 \times 10^{-9} \text{ Wm}^{-2} \text{ sr}^{-1} \text{ m}^{-1} \text{ K}^{-4}$  is the MODIS empirical constant,  $\tau_4$  is the atmospheric transmittance at  $4 \mu\text{m}$ , and  $L_4 - L_{4b}$  are radiances at  $4 \mu\text{m}$  of the fire and background pixels (Wooster et al., 2003).

The burned analysis for this work was obtained by the Terra and Aqua combined MCD64A1 Version 6.1, a monthly global dataset gridded at 500 m that provides per-pixel burned-area and quality information (Giglio et al., 2018). The MCD64A1 mapping approach fuses 500 m Moderate Resolution Imaging Spectroradiometer (MODIS) surface reflectance imagery with 1 km MODIS active fire observations (Giglio et al., 2003, 2021b). The underlying algorithm uses a burn-sensitive Vegetation Index (VI) to create dynamic thresholds for composite data, the VI is calculated from MODIS shortwave infrared atmospherically corrected surface reflectance (bands 5 and 7) along with a measure of temporal texture (Giglio et al., 2006, 2018). The algorithm identifies and encodes the burn date for each 500-meter grid cell within individual MODIS tiles as the ordinal day of the calendar year and unburned land pixels, missing data, and water grid cells are assigned unique values (Giglio et al., 2016). In addition to the burn date, the MCD64A1 product also provides data layers for Burn Data Uncertainty, Quality Assurance, and the First and Last Day of reliable change detection for the year (Dong et al., 2013; Freeborn et al., 2011; Giglio et al., 2003, 2021b; Justice et al., 2010).

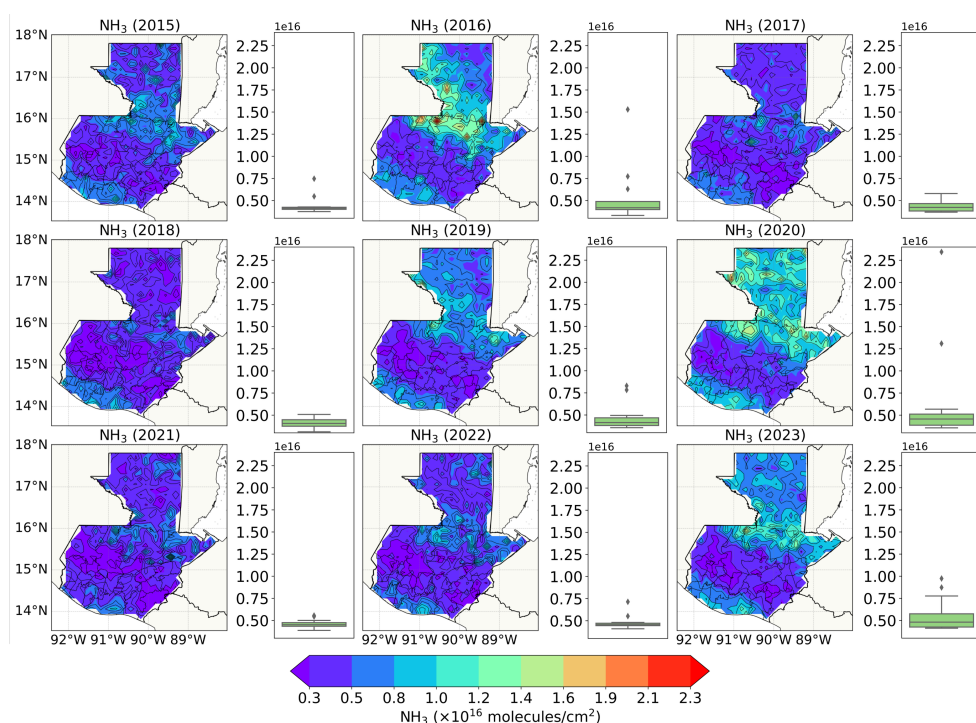

### 3 Results

#### 3.1 Spatiotemporal variability of $\text{NH}_3$

Fig. 2 shows the spatio-temporal variability of annual mean atmospheric  $\text{NH}_3$  concentrations over Guatemala from 2015 to 2023, based on concatenated data from the IASI A/B/C sensors. The respective boxplots reveal a generally stable  $\text{NH}_3$  concentration throughout the study period. However, the annual mean  $\text{NH}_3$  concentrations varied, reaching a minimum of  $4.12 \times 10^{15} \text{ molecules/cm}^2 \pm 5.34 \times 10^{14} \text{ molecules/cm}^2$  in 2018 and a maximum of  $6.67 \times 10^{15} \text{ molecules/cm}^2 \pm 5.62 \times 10^{15} \text{ molecules/cm}^2$  in 2020. The highest annual amounts were observed in 2016 ( $5.46 \times 10^{15} \text{ molecules/cm}^2$ ), 2020 ( $6.67 \times 10^{15} \text{ molecules/cm}^2$ ), and 2023 ( $5.60 \times 10^{15} \text{ molecules/cm}^2$ ), with values fluctuating around a consistent central tendency of  $4.97 \times 10^{15} \text{ molecules/cm}^2$  (Table S1). Furthermore, the analysis identifies some notable outliers, particularly in the year 2020, which recorded the highest concentration of  $2.34 \times 10^{16} \text{ molecules/cm}^2$ , followed by 2016 ( $1.53 \times 10^{16} \text{ molecules/cm}^2$ ), and 2023 ( $9.74 \times 10^{15} \text{ molecules/cm}^2$ ), indicating substantial variability and peak emissions. The median  $\text{NH}_3$  column densities remained relatively consistent throughout the years. The interquartile range (IQR), representing the spread of the central 50% of the data, also shows limited variability indicating a degree of stability in  $\text{NH}_3$  emission levels. Standard deviations are typically below  $1.00 \times 10^{15} \text{ molecules/cm}^2$ , which further reinforce the low interannual variability.

The concatenated data from IASI A/B/C data of spatial distribution of annual mean of  $\text{NH}_3$  emissions across Guatemala from 2015 to 2023 exhibited a consistent pattern of elevated emissions in the northern and southern regions. A consistent spatial pattern of elevated  $\text{NH}_3$  concentrations was observed, with discernible hotspots in the northern, north-central, and southern regions of the country. Conversely, the central midlands and highlands consistently displayed lower emission rates throughout the period. Annual mean concentrations varied significantly, with the highest values detected in 2020 and 2016. Specifically, the maximum value was observed in 2020, followed by 2016 and 2023. Despite these variations in overall annual mean concentrations, the spatial pattern of the hotspots remained consistent throughout the years. For instance, even during a year with a lower overall annual mean like 2018, increased hotspot values were still evident in the southern region of Guatemala.

**Figure 2: Annual means area-wide and boxplot of  $\text{NH}_3$  emission ( $\times 10^{16}$  molecules/ $\text{cm}^2$ ) over Guatemala (2015–2023) from IASI A, B and C.**

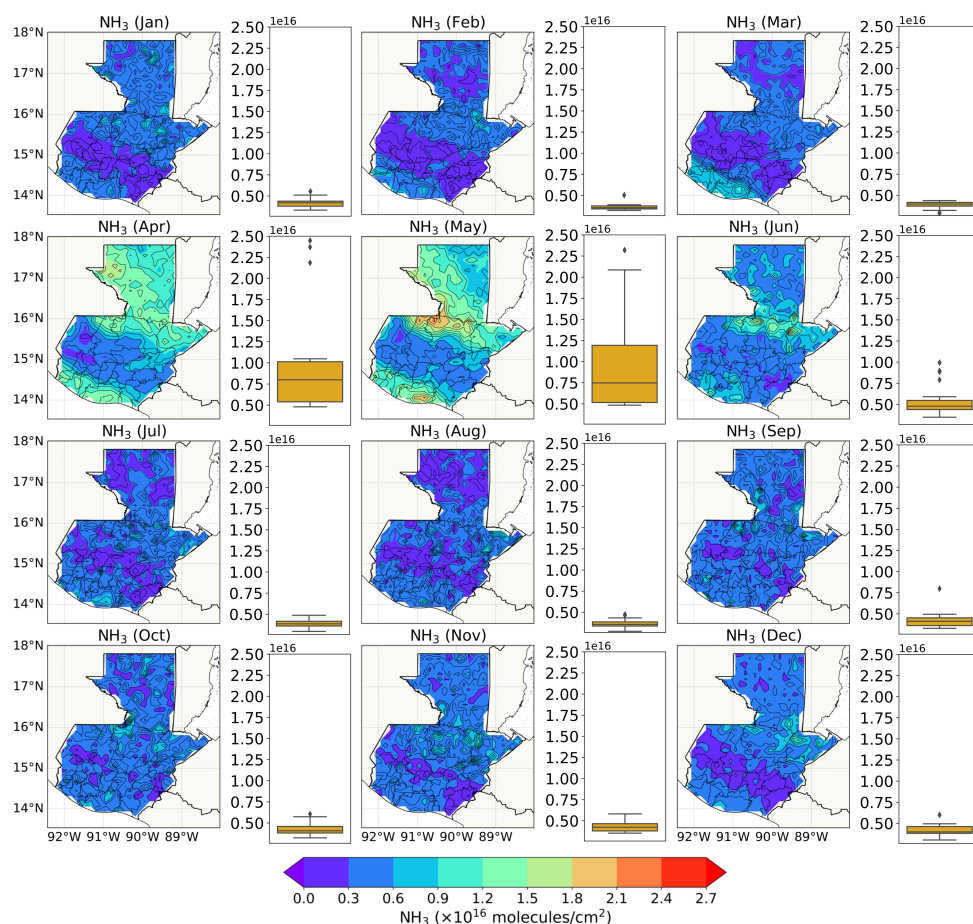

The mean monthly variation in atmospheric  $\text{NH}_3$  emission over Guatemala reveals a distinct intra-annual pattern (Fig. 3). The analysis reveals a distinct pattern in  $\text{NH}_3$  emissions with levels remaining relatively low and stable from January to March (Table S2) with monthly mean concentrations ranging from  $3.59 \times 10^{15}$  molecules/ $\text{cm}^2 \pm 1.7 \times 10^{15}$  molecules/ $\text{cm}^2$  (February) to  $4.21 \times 10^{15}$  molecules/ $\text{cm}^2 \pm 2.04 \times 10^{15}$  molecules/ $\text{cm}^2$  (January). A substantial increase in  $\text{NH}_3$  is observed at the beginning of April, with monthly mean values of  $1.01 \times 10^{16}$  molecules/ $\text{cm}^2 \pm 4.43 \times 10^{15}$  molecules/ $\text{cm}^2$  and in May with values of  $9.80 \times 10^{15}$  molecules/ $\text{cm}^2 \pm 4.49 \times 10^{15}$  molecules/ $\text{cm}^2$ . These months also show the highest values in April reaching  $2.33 \times 10^{16}$

295 molecules/cm<sup>2</sup> and May peaking at  $2.72 \times 10^{16}$  molecules/cm<sup>2</sup> respectively, indicating both significantly higher average emissions and larger variability. Emissions then exhibit a sharp decline from June onwards, with the monthly mean dropping to  $5.77 \times 10^{15}$  molecules/cm<sup>2</sup>, returning to consistently stable concentrations by July ( $3.81 \times 10^{15}$  molecules/cm<sup>2</sup>) and remaining low through December, with monthly means hovering around  $4.0 \times 10^{15}$  molecules/cm<sup>2</sup>. Sporadic outliers, representing instances of unusually high NH<sub>3</sub> emissions, are observed primarily during the April–May, corresponding to the months with the highest recorded maximum values.

300 The corresponding spatial distribution of monthly mean NH<sub>3</sub> emissions also displays the distinct seasonal pattern in concentration over Guatemala. From January to March, NH<sub>3</sub> concentrations are generally low across the country, with limited areas exhibiting elevated values. A substantial increase in both the magnitude and spatial coverage of NH<sub>3</sub> emissions is observed in April, with widespread elevated concentrations particularly in the northern and southern coastal regions, consistent with the highest monthly mean. This peak in emission intensity continues into May, maintaining high concentrations in these areas, aligning with its monthly mean located in northern and southern regions. Subsequently, a sharp decline in NH<sub>3</sub> concentrations is evident from June onwards, returning to consistently low levels by July and remaining stable through December. During these low-emission months, the spatial distribution of NH<sub>3</sub> is characterized by few hot-spots but and generally uniform low concentrations across the central midlands and highlands. This pronounced seasonality in spatial patterns aligns with the temporal variations observed in the overall time series.

305

**Figure 3: Monthly means area-wide and boxplot of  $\text{NH}_3$  emission ( $\times 10^{16}$  molecules/ $\text{cm}^2$ ) over Guatemala (2015–2023) from IASI A, B and C.**

### 3.2 Land cover classification driven a k-means clustering of $\text{NH}_3$ emissions

The spatial distribution of  $\text{NH}_3$  emissions in Guatemala, based on the overall annual mean for the period 2015–2023, reveals six distinct hotspots (Fig. 4a). One of these high-emission areas is located in the southern region of the country in the department of Escuintla, while the remaining five are concentrated in the northern region. Among them, the most prominent hotspot is Area 4, situated within the departments of Alta Verapaz, Petén and Quiché, which exhibits the highest annual mean  $\text{NH}_3$  values during the study period.

The k-means clustering partitions the country into three emission zones (Fig. 4b), each with distinct land cover profiles when integrated with ESRI data (Fig. 4c). Cluster 1 (red) associated to the highest  $\text{NH}_3$  concentrations, is located in the northern, central-north, and southern regions and is dominated by cropland (16.7%; 4710.8  $\text{km}^2$ ) and rangeland (24.5%; 6934.2  $\text{km}^2$ ).

Tree cover remains extensive (53.2%; 15,024.6 km<sup>2</sup>), while built-up areas are limited (3.4%; 948.6 km<sup>2</sup>) as shown in Fig. 4d.

325 This composition reflects the strong role of intensive agricultural activity, particularly fertilizer use and livestock, in driving the elevated emissions observed in this cluster. The complete land cover distribution across clusters is provided in Table 1.

Cluster 2 (yellow) represents moderate emission zones forming a transition around Cluster 1 and extending into northern, eastern, and southwestern Guatemala (Fig. 4e). It is dominated by tree cover (58.9%; 26,891.6 km<sup>2</sup>) and rangeland (30.3%; 330 13,844.6 km<sup>2</sup>), with a comparatively small share of cropland (6.0%; 2724.7 km<sup>2</sup>). Built-up areas account for 2.8% (1261.8 km<sup>2</sup>), slightly larger in absolute terms than in Cluster 1. This land covers mix of forests, shrublands, and transitional agricultural areas reflect semi-natural landscapes under moderate anthropogenic influence.

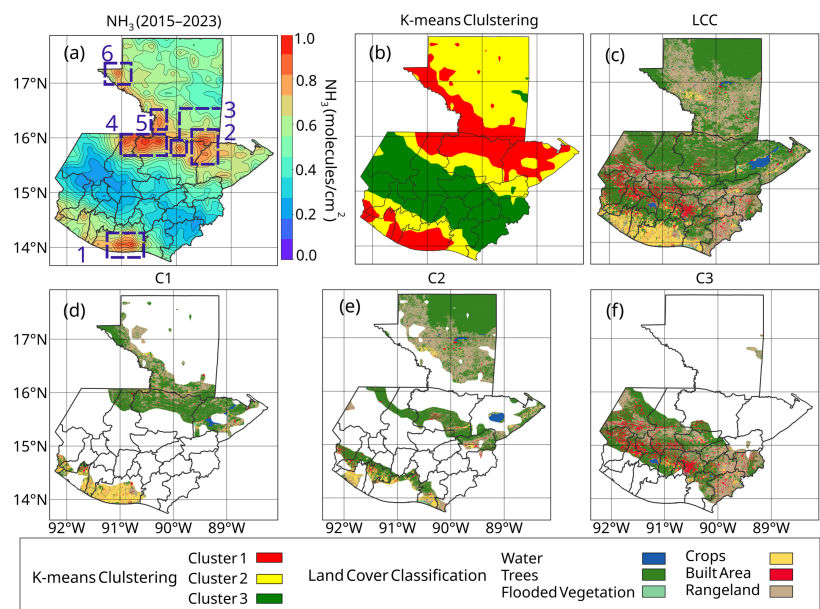

Cluster 3 (green), associated with the lowest NH<sub>3</sub> concentrations, covers the central, southern, and western regions. It is 335 characterized by high rangeland cover (34.3%; 11,893.3 km<sup>2</sup>) and substantial tree cover (47.1%; 16,298.9 km<sup>2</sup>), while cropland is minimal (3.1%; 1088.6 km<sup>2</sup>) (Fig. 4f). Notably, built-up areas occupy the largest proportion across clusters (14.8%; 5137.1 km<sup>2</sup>), despite Cluster 3 having the smallest territorial extent. The coexistence of dense vegetation, moderate agricultural activity, and significant urban development suggests a complex anthropogenic footprint, though with lower NH<sub>3</sub> emissions than in Cluster 1.

340

Overall, Cluster 1 covers the smallest area (28,253.9 km<sup>2</sup>) compared to Cluster 2 (45,662.3 km<sup>2</sup>) and Cluster 3 (34,640.0 km<sup>2</sup>), yet it exhibits the highest NH<sub>3</sub> emissions. This elevated level is strongly associated with its land cover composition, particularly the concentration of cropland and rangeland.

345 **Table 1: Land cover composition of percentage and area for the different cluster in Guatemala.**

	Cluster 1		Cluster 2		Cluster 3	
LCC	Percentage %	Area km <sup>2</sup>	Percentage %	Area km <sup>2</sup>	Percentage %	Area km <sup>2</sup>
<b>Water</b>	1.94	548.97	1.78	812.44	0.64	221.61
<b>Trees</b>	53.16	15,024.57	58.89	26,891.61	47.05	16,298.85
<b>Flooded Veg.</b>	0.31	86.77	0.28	127.16	0	0.63
<b>Crops</b>	16.67	4710.8	5.97	2724.67	3.14	1088.56
<b>Built Areas</b>	3.36	948.62	2.76	1261.81	14.83	5137.06
<b>Rangeland</b>	24.53	6934.19	30.32	13,844.63	34.33	11,893.31

(c) ESRI Land Use/Land Cover across Guatemala, categorized into three clusters based on k-means combined with land cover types: water, trees, flooded vegetation, crops, built area, and rangeland, (d) C1 related to cluster 1, (e) C2 to cluster 2, and (f) C3 to cluster 3.

### 3.3 Fires

In order to connect the previously described ammonium patterns Fig. 5 shows the annual distribution of fires in Guatemala during the study period. The data reveal considerable interannual variability observed in both the number and distribution of fires, with mean monthly fire counts ranging from a minimum of 73 in 2022 to a maximum of 162 in 2016 (Table S3). During 2015, the mean monthly number of fires was 137, with a monthly maximum of 817 fires. Fire activity peaked in 2016 with the highest mean monthly count (162), followed by 2017 with 149. Notably, 2017 also recorded the highest monthly peak of 947 fires, indicating both more frequent and more intense fire events compared with the surrounding years.

In 2018, fire activity decreased sharply, with the mean monthly count dropping to 77 and the maximum monthly count to 383. The activity increased in 2019 (mean 133) and remained elevated in 2020 (mean 142), when the highest single month value of the entire study period was observed (957), coinciding with the COVID-19 pandemic. From 2021 onward, the number of fires generally shows a decreasing trend, with mean monthly counts dropping to 82 in 2021 and reaching its minimum of 73 in 2022 (maximum 247). Although 2023 showed a partial increase with mean of 119 and maximum 564, (with a maximum of 564), fire activity did not return to higher levels recorded from 2015-2020 period.

The spatial distribution of Fire Radiative Power (FRP) across Guatemala from 2015 to 2023 complements the annual fire counts, showing both significant interannual variability and spatial heterogeneity in fire activity. Years with elevated fire frequencies, such as 2017, 2019, 2020 and 2023, were also marked by widespread areas of moderate to high FRP, with hotspots concentrated in the northern and southern regions. In contrast, years of reduced fire counts, including 2018, 2021 and 2022, coincided with lower FRP intensity and a more limited spatial extent. These consistent patterns indicate fluctuating fire regimen, where periods of intense and widespread fire activity alternated with years of reduced activity.

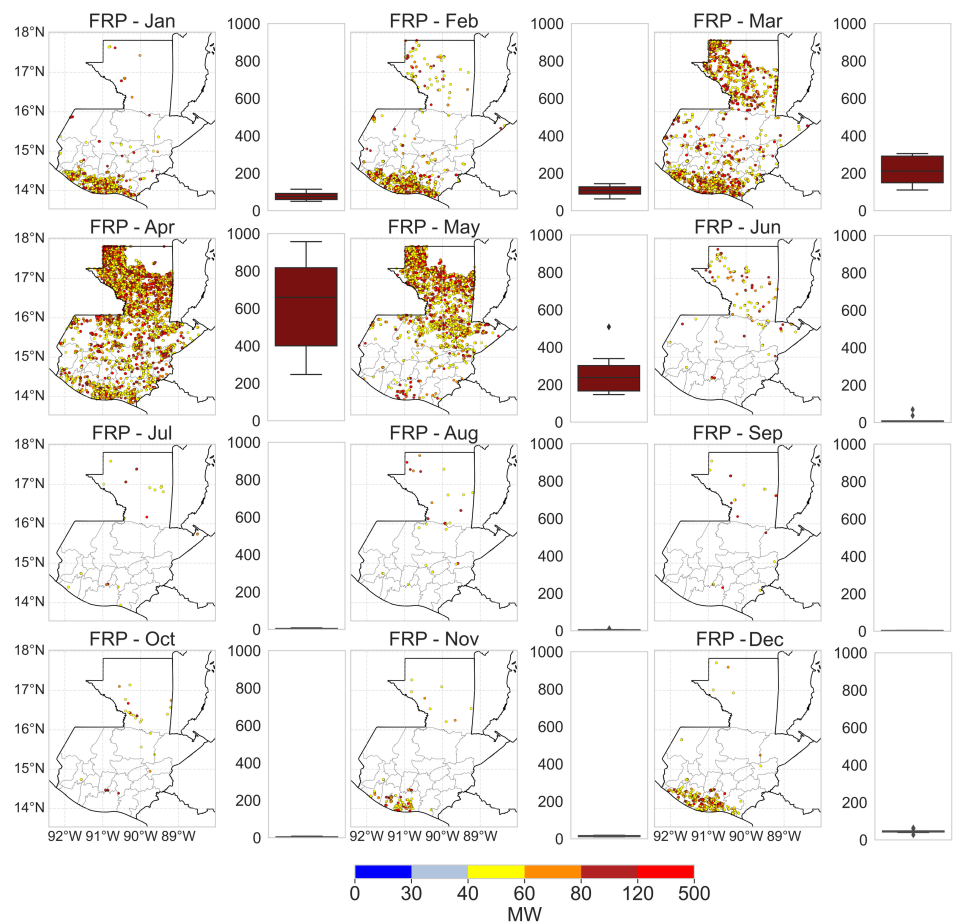

**Figure 5: Mean monthly fire counts distribution and boxplot of detected fires over Guatemala (2015–2023), filtered by nominal confidence level >70% and fire radiative power >40 MW, values represent the annual distribution of fire activity.**

The spatial distribution and box plots illustrate the monthly fires activity in Guatemala (Fig. 6). A clear seasonal pattern in fire occurrence is obvious. Fire activity is relatively low at the start of the year, with a monthly mean of 77 fires in January (maximum of 114), gradually increasing in February to a mean of 105 fires (maximum 144). A substantial rise in fire activity occurs in March, with a mean of 211 fires (maximum 305). April marks the peak of fire activity, recording the highest monthly mean of 635 fires and the highest maximum of 957 fires indicating the strongest variability and largest IQR. Although fire activity remains elevated in May, with a mean of 261 fires (maximum 509), before declining sharply in June to a mean of 15 fires and a maximum of 69. The lowest fire activity occurs in September, with a mean of 3 fires and a maximum of only 5 until a slight increase in fire activity returns from December (mean of 46, maximum of 64). The remaining months, July to November, generally exhibit low fire activity, with monthly means below 15 fires (Table S4).

390 The spatial distribution of FRP across Guatemala also confirms this seasonal pattern and shows the shifts in fire location and intensity. During the early months of the year, from January to March, fire activity is concentrated mainly in the southern regions, particularly in the department of Escuintla and adjacent lowland areas. As the season advances, fire activity shifts northward reaching a peak in April. During this period, both the intensity and spatial extent of fires increase markedly with widespread high-intensity events, particularly across the northern and central regions. From June onwards, a decrease in FRP  
395 hotspot areas is evident. Fire activity decreases substantially, with only a few moderate-intensity events observed in localized areas in the northern part (department of Petén). This trend continues through the later months of the year, from July to October, when fire activity reaches its minimum. In November and December fire activity remerged marking the beginning of the next fire season.

400

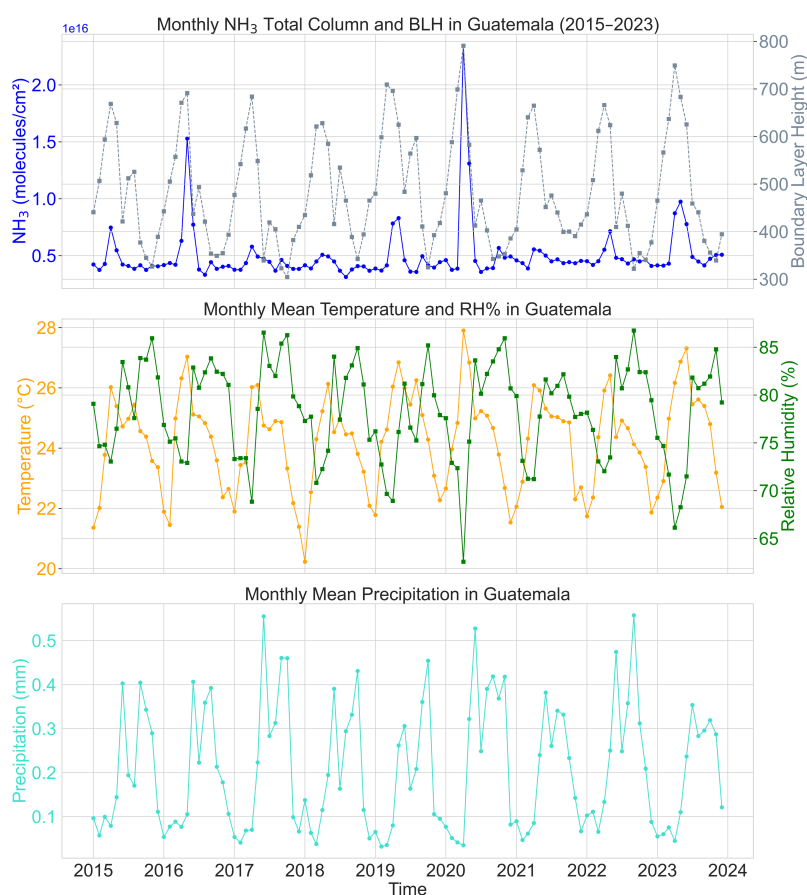

**Figure 6: Mean monthly fire counts distribution and boxplot of detected fires over Guatemala (2015–2023), filtered by nominal confidence level >70% and fire radiative power >40 MW, values represent the annual distribution of fire activity.**

### 3.4 Meteorology

405 Figure 7 illustrates the time series of monthly  $\text{NH}_3$  concentrations, planetary boundary layer height (m), temperature ( $^{\circ}\text{C}$ ), relative humidity (%), and total precipitation (mm) from 2015 to 2023. All the variables exhibit a clear seasonal pattern, with  $\text{NH}_3$  concentrations and PBLH generally peaking in the middle of each year, which points to a general inverse relationship where higher  $\text{NH}_3$  concentrations tend to coincide with lower PBLH values, and vice versa. This pattern suggests that a shallower boundary layer, which restricts the vertical dispersion, leads to an accumulation of  $\text{NH}_3$  near the surface.

410

**Figure 7: Time series of  $\text{NH}_3$  emission (blue line) and meteorological monthly means in Guatemala of atmospheric planetary boundary layer height (PBLH) (light gray line), relative humidity (%) (green line), temperature ( $^{\circ}\text{C}$ ) (yellow line) and precipitation (mm) (turquoise line).**

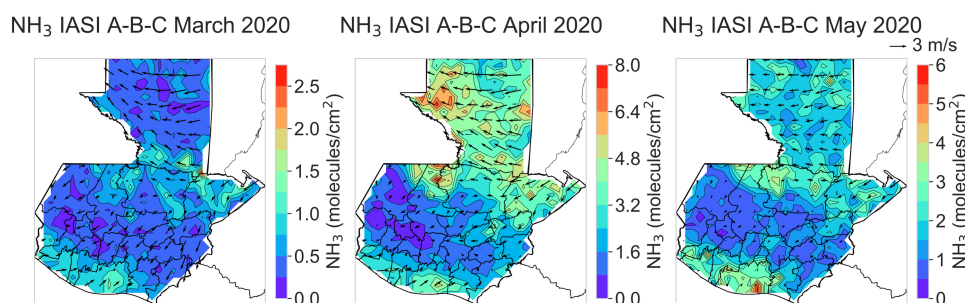

415

### 3.5 Case Study of NH<sub>3</sub> Emission

NH<sub>3</sub> anomalies were observed in Guatemala in April 2020, marking the highest emission levels recorded during the study period with a monthly means detected by IASI A ( $2.32 \times 10^{16}$  molecules/cm<sup>2</sup>), B ( $2.48 \times 10^{16}$  molecules/cm<sup>2</sup>) and C ( $2.43 \times 10^{16}$  molecules/cm<sup>2</sup>). This peak is particularly noteworthy as it occurred shortly after the implementation of COVID-19 lockdown measures in March 2020, which significantly reduced transportation and industrial activity (Fig. S4).

The monthly mean spatial distribution of NH<sub>3</sub> during April 2020 reveals distinct hotspots concentrated in the northern and southern regions of Guatemala. The most affected location is the department of Petén (max.  $7.8 \times 10^{16}$  molecules/cm<sup>2</sup>) and Quiché. Furthermore, In May, a hotspot emerged in the southern, particularly in the department of Escuintla, where concentration reached  $5.9 \times 10^{16}$  molecules/cm<sup>2</sup> (Fig. 8).

The corresponding environmental conditions, including wind vectors meter over second (m/s), further clarify the dynamics of NH<sub>3</sub> dispersion. Strong easterly winds ( $\sim 3$  m/s) dominated the northern region, facilitating long-range transport of NH<sub>3</sub>, while central Guatemala experienced moderate to stagnant wind conditions that likely favored local accumulation. Similarly, wind patterns were present in March and May 2020, although wind speed decreased in May. Notably, the increase in NH<sub>3</sub> concentrations in southern Guatemala during May coincided with weaker wind activity.

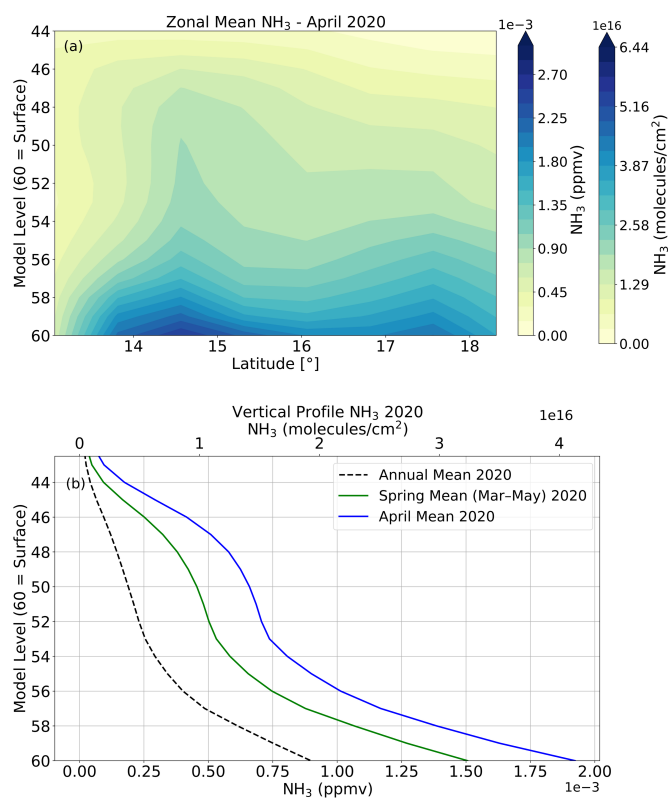

**Figure 8: Monthly mean area-wide of NH<sub>3</sub> ( $\times 10^{16}$  molecules/cm<sup>2</sup>) with wind mean vectors over Guatemala (March, April and May 2020).**

To disentangle surface driven emissions from atmospheric transport mechanisms, we analyzed the vertical and latitudinal distribution of atmospheric NH<sub>3</sub> using zonal means and vertical profiles over Guatemala. This approach allows us to assess surface emissions, transport, and dilution processes. Figure 9a shows a cross-section of NH<sub>3</sub> mass mixing ratios throughout the atmosphere (model level 60 to 44) along the latitudes of Guatemala as a zonal mean. It highlights a greater abundance of NH<sub>3</sub> in both the northern and southern regions, with concentrations primarily confined to the lower atmospheric levels. Furthermore, the NH<sub>3</sub> concentrations vary with both latitude and altitude, the highest concentrations of NH<sub>3</sub> are observed at lower model levels (below approximately level 45), this demonstrates that NH<sub>3</sub> is primarily concentrated near the surface.

Specifically, the highest mass mixing ratios are found between 14°N and 15°N latitude, while north of 15°N the NH<sub>3</sub> concentration decreases with increasing latitude and at latitudes south of 14°N, the plot shows lower concentrations.

Fig. 9b further illustrates the area-average vertical profiles of NH<sub>3</sub> concentrations for April (blue line), spring (March – May, green line) and the entire year 2020 (black dashed line). The vertical axis is represented in model levels, where level 60 corresponds to the surface and decreasing levels indicate increasing altitude in the model coordinate system. While model levels are not fixed to physical altitudes, model level 60 typically corresponds to near-surface conditions (~0–100 m), and model level 40 is approximately situated around 5–7 km above sea level, depending on surface pressure and atmospheric stratification. The vertical profile of NH<sub>3</sub> shows the April 2020 mean (blue line) with  $1.93 \times 10^{-3}$  parts per million by volume (PPMV) ( $\sim 4.0 \times 10^{16}$  molecules/cm<sup>2</sup>), the spring mean (March–May 2020, green line) of  $1.55 \times 10^{-3}$  PPMV ( $\sim 3.3 \times 10^{16}$  molecules/cm<sup>2</sup>) and the annual mean for 2020 (black dashed line) with  $0.90 \times 10^{-3}$  PPMV ( $\sim 1.9 \times 10^{16}$  molecules/cm<sup>2</sup>) respectively. The profile reveals that NH<sub>3</sub> concentrations were highest near the surface (model level 60) during April, gradually decreasing with altitude, likely due to dilution as emissions dispersed upward mainly driven by intense wildfire activity during this period.

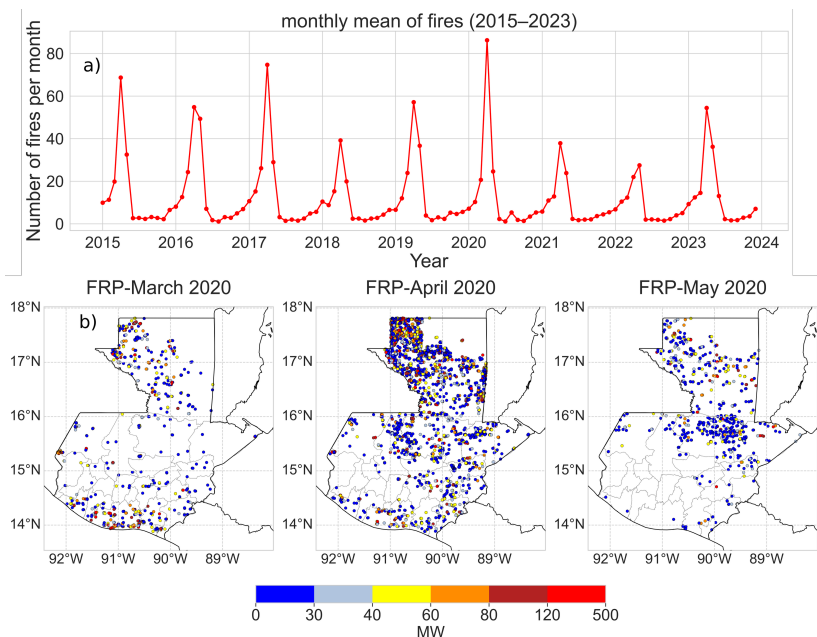

**Figure 9: (a) zonal mean mass mixing ratio across latitudinal bands (model level 60 to 44) for April 2020 and (b) vertical profile of NH<sub>3</sub> for April (blue line), spring (March – May, green line) and the entire year 2020 (black dashed line) over Guatemala.**

### 3.6 Fires and burned areas

Fire activity in spring 2020 showed an anomalous peak compared to the long-term pattern. As mentioned above, March to  
465 May indicate a general peak phase in fire activities in Guatemala. With respect to spring 2020. April 2020 recorded the highest  
number of active fires across Guatemala throughout the entire study period (957), representing a significant anomaly in the  
observed annual cycle (Fig. 10a). The FRP distribution illustrate this anomaly, in April, fires were not only more numerous  
but also more spatial extensive, covering both the northern lowlands (Petén) and the central regions of Guatemala, with many  
highly intensive events ( $>100$  MW). By contrast, March fires were fewer and spatially scattered, while May showed a decline  
470 in both intensity and spatial coverage, though localized cluster persisted, particularly in the department of Alta Verapaz (central  
north) (Fig. 10b). This spatial and temporal concentration of intense fire activity in April 2020 coincides with the exceptional  
 $\text{NH}_3$  anomalies observed during the same month.

This case study demonstrates that April 2020 was not only the climatological peak of the fires season but also exceptionally  
475 severe, with both higher-than-average fire intensity and an expanded spatial footprint compared to other years. This assessment  
of fire intensity and spatial extent was conducted using a confidence level exceeding 70%, thereby enhancing the  
representativeness and reliability of the observed data.

480 **Figure 10: a) Monthly time series of mean fires, and b) area-wide distribution of mean fires over the study period over Guatemala with confidence level over 70%.**

The spatial distribution of burned areas highlights intense fire activity in the northern region of Guatemala (Fig. 11), particularly across multiple days in April 2020. It is striking that the burned areas are located in the northern and southern areas, which are mainly used for agriculture. The most significant burning occurred between April 24 to April 29 when large contiguous burned area were detected located in Petén, covered approximately 53.8 km<sup>2</sup>. The province most severely affected by burned areas was Petén (northern part), suggesting a concentrated fire event during this late-April period. The total burned area between April and May 2020 was approximately 1,485.6 km<sup>2</sup> (red), representing about 1.36% of Guatemala's national territory.

**Figure 11: Burned areas during the months of April and May 2020.**

#### 4 Discussion

This study investigated the spatiotemporal dynamics of atmospheric NH<sub>3</sub> emissions from IASI A/B/C sensor data, over Guatemala between 2015–2023 using multi-satellite observations combined with fire, land cover, and meteorological datasets. Based on a case study in April 2020, fire events were linked to agricultural and meteorological anomalies. The observed spatiotemporal variability reflects both consistent long-term patterns and distinct episodic anomalies (Fig. 2). Annual median concentrations remained relatively constant with ( $4.98 \times 10^{15}$  molecules/cm<sup>2</sup>), with limited variability in the interquartile range and overall standard deviations around  $1.74 \times 10^{15}$  molecules/cm<sup>2</sup>. This stability suggests that background NH<sub>3</sub> emissions in Guatemala are relatively constant, likely dominated by persistent sources such as agriculture (fertilizer application and

livestock), which account for the majority of global  $\text{NH}_3$  emissions (McDuffie et al., 2020; Sutton et al., 2013). Nevertheless, the analysis also identified years with substantially elevated  $\text{NH}_3$  levels, particularly 2016, 2020, and 2023, which exhibited both higher annual means and extreme values. Among these years, 2020 recorded the highest annual average ( $6.67 \times 10^{15}$  molecules/ $\text{cm}^2$ ) and the most extreme single event anomaly ( $2.34 \times 10^{16}$  molecules/ $\text{cm}^2$ ) (Table S1).

The seasonal cycle further illustrates this relationship between emissions and seasonal meteorological conditions with concentrations reaching their lowest levels between June–October (Fig. 3). Concentrations were low during October–December (mean  $\sim 4.3 \times 10^{15}$  molecules/ $\text{cm}^2$ , maximum mean  $> 1.6 \times 10^{16}$  molecules/ $\text{cm}^2$ ), but increased steadily from January, peaking in April–May (mean  $\sim 1.0 \times 10^{16}$  molecules/ $\text{cm}^2$ , maximum mean  $> 2.3 \times 10^{16}$  molecules/ $\text{cm}^2$ ). This period corresponds with the Central American fire season, during which  $\text{NH}_3$  emissions intensify. Following this peak, the monthly mean  $\text{NH}_3$  concentrations decreased dramatically by approximately 42.0% in June. The sharp decline after June reflects the onset of the rainy season, when fires diminish and wet deposition increases (Ríos and Raga, 2018). Persistent  $\text{NH}_3$  hotspots were detected in the northern (Petén, and Quiché, mean  $\sim 2.2 \times 10^{16}$  molecules/ $\text{cm}^2$ ) and southern (Escuintla, mean  $\sim 2.1 \times 10^{16}$  molecules/ $\text{cm}^2$ ) areas of Guatemala characterized by intensive cropland, rangeland, and repeated fires occurrence across years. In contrast, the highlands and central regions showed lower values (mean  $\sim 5.0 \times 10^{15}$  molecules/ $\text{cm}^2$ ). Even in relatively low-emission years such as 2018 (annual mean  $4.12 \times 10^{15}$  molecules/ $\text{cm}^2$ ), localized southern hotspots persisted during the fire season, underlining the influence of spatially concentrated emission sources. These findings align with global studies showing strong seasonal patterns in  $\text{NH}_3$  emissions, reflecting fertilizer application timing and biomass burning (Van Damme et al., 2018, 2021; Fortems-Cheiney et al., 2016; Saravia and Trachte, 2025). The results highlight that while agriculture provides a stable emission baseline, episodic fire activity acts as a seasonal amplifier of  $\text{NH}_3$  variability.

The cluster analysis further highlights the strong influence of land cover composition on  $\text{NH}_3$  variability across Guatemala (Fig. 4). Particularly Cluster 1, dominated by cropland and rangeland, consistently exhibited the highest concentrations, reinforcing the role of fertilizer application and livestock as persistent emission sources. Although it covers the smallest area, its intensively managed agricultural mosaics contributed disproportionately to national emissions, demonstrating how local land-use practices can have regional impacts on the atmosphere. In contrast, Cluster 2 (extensive forest and transitional agriculture) and Cluster 3 (urban, rangeland, forest areas) showed moderate and low  $\text{NH}_3$  levels, respectively. The observed gradient among clusters suggests that agricultural intensity, rather than the presence of urbanization or semi-natural landscapes, primarily drive the  $\text{NH}_3$  variability. Comparable spatial patterns have been reported for other agricultural regions, like South Asia, where cropland dominated areas exhibited enhanced  $\text{NH}_3$  emission (Abeed et al., 2022). Also, in Western Europe higher levels of  $\text{NH}_3$  were found which were linked to intensive livestock production and the use of fertilizer (Van Damme et al., 2018). Moreover, small but intensively managed cropland and rangeland mosaics disproportionately contribute to national emissions, reinforcing the role of regional hotspots. The temporal overlap of maximum  $\text{NH}_3$  concentrations with fire counts and FRP underscores biomass burning as a major episodic source (Fig. 5). Peak years such as 2016, 2017, and 2020 mirrored

elevated  $\text{NH}_3$  anomalies, while reduced fire activity in 2018 and 2021–2022 coincided with lower emissions. Similar patterns were reported for Amazonia, where  $\text{NH}_3$  emission from biomass burning exhibit strong spatial and temporal variability, with interannual peak linked to severe droughts and late fire-season activity, highlighting the influence of El Niño-Southern Oscillation (ENSO) events (Whitburn et al., 2017) and Southeast Asia, particularly Indonesia, largely human-induced fires for  
 540 land clearing burned extensive tropical forest and peatlands, releasing substantial  $\text{NH}_3$  emissions, which were further amplified by strong ENSO conditions (Chang et al., 2021; Whitburn et al., 2016b).

Guatemalan fire driven  $\text{NH}_3$  peaks appear to be predominantly human caused. (FAO, 2007) reports that most fires worldwide are anthropogenic, and in Central America, lightning is minimal during November–April, precisely when fire activity is highest  
 545 (Kucieńska et al., 2010). Practices such as burning to stimulate pasture regrowth, suppress vegetation, and prepare cropland (Keeley, 2002) likely explain this seasonality. However, a clear interannual variability in both fire counts and intensity, could be observed (Fig. 5). 2016 and 2017 recorded the highest fire frequencies, with 2017 also producing the most extreme monthly peak before 2020. In contrast 2018 and 2022 were marked by sharp declines in activity. The elevated fire activity in 2016–2017 coincided with warmer and relatively drier conditions across Guatemala. Annual mean temperatures reached  $24.16^\circ\text{C}$   
 550 (2016) and  $23.9^\circ\text{C}$  (2017) as shown in Fig. S5, consistent with (INSIVUMEH, 2023) ground observations of  $24.5^\circ\text{C}$  and  $24.3^\circ\text{C}$ , respectively. Similarly, precipitation totals were below average, indicating  $0.19\text{--}0.23\text{ mm day}^{-1}$  (Fig. S6) and INSIVUMEH reporting  $1850\text{--}2100\text{ mm year}^{-1}$ , compared to wetter years such as 2020 and 2022 ( $>2300\text{ mm year}^{-1}$ ). These conditions followed the 2015–2016 ENSO episode (Anderson et al., 2023), which induced drought stress and elevated surface temperatures throughout Guatemala, thereby increasing fire susceptibility. Similar ENSO driven fire and  $\text{NH}_3$  anomalies have  
 555 been reported in other tropical regions. Particularly in Indonesia, where Whitburn et al. (2016) documented a doubling of annual  $\text{NH}_3$  emissions during the 2015 El Niño due to extensive peatland fires. Such ENSO related drought anomalies have been shown to intensify biomass burning and  $\text{NH}_3$  emissions by reducing vegetation moisture and fuel humidity (Burton et al., 2020). In contrast, cooler and wetter years such as 2018 and 2022 coincided with reduced fire activity and lower  $\text{NH}_3$  emissions, emphasizing that meteorological variability modulated by ENSO phases.

560 To further illustrate this fire– $\text{NH}_3$  connections under contrasting meteorological conditions, the most extreme fire anomaly during the study period (April 2020, Fig.10) was selected for detailed analysis. This month exhibited exceptionally high fire counts and FRP, corresponding with a pronounced  $\text{NH}_3$  peak record. Especially in the northern (Petén) and southern (Escuintla) regions, fire occurrences reached up to 957 hotspots, confirming the spatial coincidence between biomass burning and enhanced  $\text{NH}_3$  concentrations. This event represents a critical episode of regionally intensified emissions, likely driven by  
 565 prolonged dry conditions during April 2020, despite being characterized by near-neutral ENSO conditions (annual precipitation in 2020 =  $2,350\text{ mm}$ , INSIVUMEH) and above the average temperatures ( $24.6^\circ\text{C}$ ). According to INSIVUMEH, 2020 was the third hottest year of the study period and recorded the highest total precipitation. Moreover, the atmospheric

boundary layer height during April 2020 exhibited one of the lowest mixing layer heights of the entire period (Fig. 7), which  
570 likely contributed to the accumulation and enhanced detection of  $\text{NH}_3$  emissions in the lower atmosphere.

Despite reduced traffic and industrial activity under COVID-19 lockdowns,  $\text{NH}_3$  concentrations reached unprecedented levels  
due to widespread, intense fires activity (Fig. S4). Meteorological conditions during this period showed that emissions  
remained confined to the lower troposphere, below model level 54 (altitude approximately  $<1$  km), indicating surface-driven  
575 emissions with limited vertical mixing, which favors the accumulation of  $\text{NH}_3$  (Fig. 9). Weak wind circulation during April  
2020 further constrain dispersion, particularly across the central and northern regions, enhancing the local emissions. Overall,  
approximately  $1,486 \text{ km}^2$  were affected (1.36% of national territory), mostly in agricultural landscapes (Petén) (Fig. 11).  
Notably, most of these burned areas were located in the northwest of Guatemala, within the officially designated protected  
areas that correspond to the large Maya Biosphere reserve (CONAP, 2016), underscoring the ecological and regulatory  
580 implications of such extreme events.

## 5 Conclusion

This study provides the first integrated spatiotemporal assessment of atmospheric  $\text{NH}_3$  emissions over Guatemala (2015–  
2023), using multi-satellite observations combined with fire, land cover, and meteorological reanalysis data. The results reveal  
585 distinct seasonal and interannual patterns, with  $\text{NH}_3$  concentrations peaking in April–May during the regional fire season and  
declining sharply after the onset of rainfall. Interannual variability was characterized by pronounced anomalies in 2016, 2020,  
and 2023, reflecting the combined influence of fire activity and climatic variability. Additionally, persistent hotspots were  
detected in the northern (Petén–Quiché) and southern (Escuintla) agricultural regions, driven by intensive use of fertilizer,  
livestock and widespread anthropogenic biomass burning. These agricultural areas contribute disproportionately to Guatemala  
590  $\text{NH}_3$  emissions despite their smaller spatial extent.

The analysis also highlights the role of meteorology and ENSO related anomalies in modulating  $\text{NH}_3$  variability. Warm ENSO  
phases (2015–2016 and 2023) enhanced drought stress and fire susceptibility, while favorable meteorological conditions such  
as high temperature and shallow boundary layers intensified  $\text{NH}_3$  accumulation. The April 2020 case study exemplified the  
595 linking between fire activity and  $\text{NH}_3$  emissions, when nearly  $1,500 \text{ km}^2$  burned and concentrations reached their highest levels  
of the entire record. This episode occurred under near neutral ENSO conditions but was reinforced by locally extreme dryness,  
low boundary layer height and reduced anthropogenic activity during the COVID-19 lockdown, leading to enhanced  $\text{NH}_3$   
retention in the atmosphere.

600 Overall, the findings demonstrate a dual emission regime over Guatemala, with a stable agricultural baseline overlaid by  
episodic peaks due to fires, which are modulated by climatic variability. Continuous satellite-based monitoring remains  
essential for improving emission inventories, supporting regional air quality management, and guiding strategies to reduce  
biomass burning impacts. Uncertainties remain regarding the quantification of absolute emission and the role of smaller scale  
or undocumented burning. Future work should integrate ground-based observations, finer resolution land use data, and  
605 atmospheric modeling to better constrain source contribution and transport process to understand the role of  $\text{NH}_3$  as a precursor  
to particulate matter and broader climate impacts in Central America.

### Data availability

Monthly atmospheric ammonia column products from the Infrared Atmospheric Sounding Interferometer (IASI A/B/C),  
610 versioned Level-3 data cover global grids, AERIS-IASI portal: <https://iasi.aeris-data.fr/nh3/>. Monthly atmospheric variables  
are provided by the ERA5 reanalysis dataset (<https://cds.climate.copernicus.eu/datasets/reanalysis-era5-single-levels-monthly-means?tab=download>). Active fire detections MODIS-Aqua/Terra from the NASA-Earth Observing System's Fire  
Information for Resource Management System (FIRMS) database (<https://firms.modaps.eosdis.nasa.gov/>). Burned area  
monthly L3 global 500m grid V061 (<https://www.earthdata.nasa.gov/data/catalog/lpcloud-mcd64a1-061>).
