Abstract. Science Monitoring And Reliable Telecommunications (SMART) subsea cables utilize sensors integrated within repeaters to record temperature, acceleration, and pressure on the seafloor. The planned Tamtam SMART cable will connect Vanuatu and New Caledonia across a major subduction zone. Modeling recent M_W 7.7 to 8.0 earthquakes and maximum considered M_W 8.33 to 8.8 scenarios provides a range of seismic waveforms with realistic relative timing and long-period ground displacements at the sensor locations as well as coseismic seafloor uplift and subsidence at the sources used for tsunami excitation. A nonhydrostatic model describes tsunami generation, propagation, and scattering in the southwest Pacific. Spectral analysis of the computed tsunami waves shows multi-scale oscillations along the Vanuatu trench with periods from a few minutes to over an hour. The cable sensor locations are outside energetic antinodes of oscillation modes and the modeled tsunami amplitude is representative of the seismic source with minor interference from land masses. The suite of synthetic seismic and tsunami waveforms informs implementation of the sensor system for regional hazard monitoring. The Tamtam SMART cable, deployed in a very active tectonic environment with limited on-land instrumentation, will augment rapid earthquake and tsunami warning as well as source quantification.

1. Introduction

The last decade has seen increased interest in leveraging subsea telecommunication cables as a cost-effective means to monitor vast expanses of the ocean. There are currently 1.5 million kilometers of subsea cables in operation around the world. When existing cables are replaced or

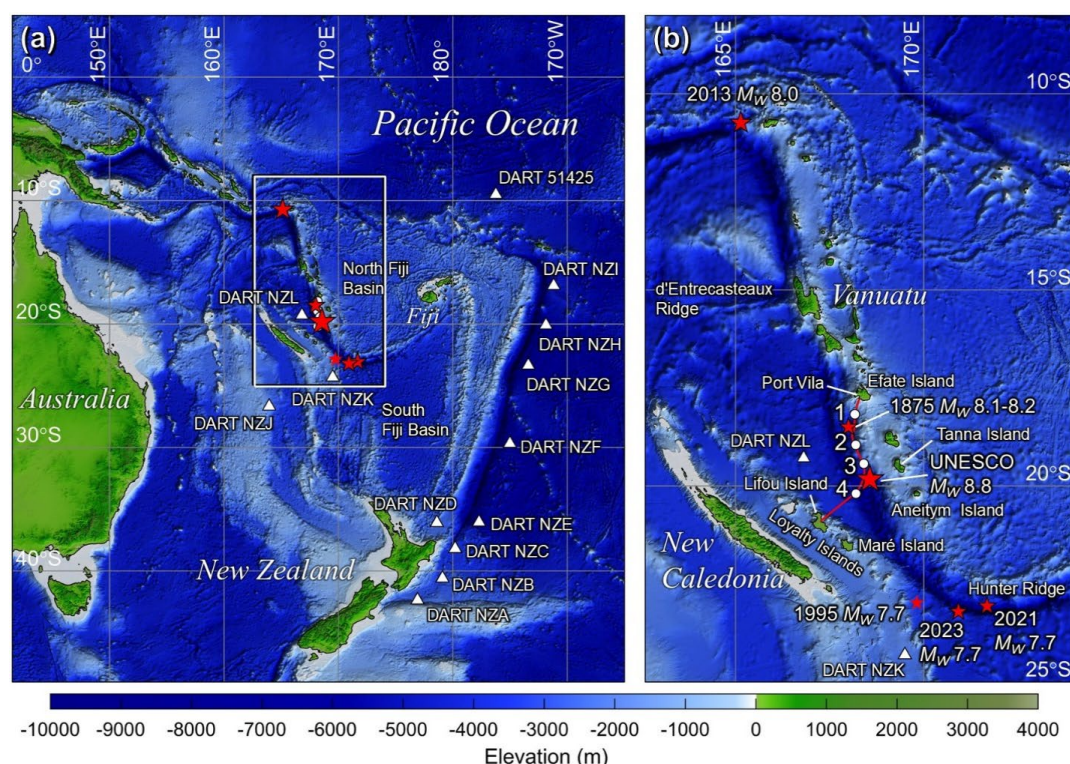

32 new routes are planned, sensors can be installed at repeaters or in separate modules to provide
33 dense measurements of temperature, acceleration, and pressure for oceanographic and climate
34 research at a modest incremental cost (Howe et al., 2019). The resulting Science Monitoring And
35 Reliable Telecommunications (SMART) subsea cables can also provide real-time data for
36 earthquake and tsunami early warning, and that has provided motivation for a number of on-going
37 projects, such as the InSEA wet demonstration project off Sicily, Italy; and the Atlantic CAM ring
38 system connecting Lisbon, Azores, and Madeira in Portugal (Howe et al., 2022).

39 Planning for the Tamtam SMART subsea cable between Vanuatu and New Caledonia in the
40 Southwest Pacific is currently underway. The system will stretch across the Vanuatu subduction
41 zone, which is very active and geologically young with frequent tsunamigenic earthquakes (Roger
42 and Pelletier, 2024). The planned cable route extends from Port Vila, the capital of Vanuatu on
43 Efate Island, along the archipelago to the south before crossing the trench to reach an existing
44 landing station on Lifou Island with connectivity to the rest of New Caledonia (Fig. 1). There are
45 four sensor modules 50~90 km apart along the 450 km cable. Three sensor modules are planned
46 for the upper margin slope along the shelf edge and one at the trench to provide real-time
47 earthquake and tsunami monitoring capability near populated areas. This project is situated in a
48 region with existing seismic and sea level networks that can provide information for examination
49 of data quality and interoperability. As shown in Fig. 1a, the New Zealand DART (Detection and
50 Reporting of Tsunami) network has some coverage of tsunami waves in the Southwest Pacific
51 with stations to the west and south of the Vanuatu islands (Fry et al., 2020). Global seismic network
52 stations are rather sparsely distributed in the Southwest Pacific but are supplemented by more than
53 50 stations of the Oceania Regional Seismic Network (ORSNET) operated by South Pacific
54 countries (UNESCO-IOC, 2025).

55 Tsunamis in the region have been generated predominantly by earthquakes with volcanic and
56 non-seismic sources representing less than 5% of documented events (Roger and Pelletier, 2024).
57 Fig. 1b shows the locations of selected tsunamigenic earthquakes with regional implications. The
58 northern Vanuatu subduction zone has produced several large earthquakes in the past century. One
59 of the largest is the 6 February 2013 M_w 8.0 Santa Cruz Islands thrust faulting with shallow
60 eastward dip that generated a destructive tsunami impacting local communities (e.g., Lay et al.,
61 2013; Cleveland et al., 2014). Across the d'Entrecasteaux Ridge, the southern Vanuatu subduction
62 zone is known for strong and long-duration aftershock sequences (Ye et al., 2021), accompanying

63 major plate boundary and outer rise earthquakes (Roger et al., 2021). The largest, 1875 thrust-
 64 faulting earthquake with estimated M_W 8.1-8.2 produced sediment deposits reaching 10 m
 65 elevation on the northeastern coast of Lifou Island, New Caledonia (Paris et al., 2023), while an
 66 M_W 7.7 normal faulting event in May 1995 along the Loyalty ridge generated a tsunami with 8 m
 67 runup on Aneityum Island, Vanuatu (Roger and Pelletier, 2024).

68
 69 **Figure 1.** Location map and two levels of nested computational grids. (a) Level-1 Southwest
 70 Pacific. White rectangle indicates the level-2 grid coverage. (b) Level-2 Vanuatu subduction zone.
 71 The magenta line and white circles denote planned SMART cable and sensor locations. White
 72 triangles denote DART locations. Smaller red stars indicate epicenters of large historical and
 73 recent tsunamigenic earthquakes and the large red star indicates the maximum earthquake in the
 74 Southern Vanuatu Subduction Zone from UNESCO-IOC (2025).

75 The southernmost Vanuatu Trench curves eastward along the Hunter Ridge. The two largest
 76 M_W 7.7 earthquakes in the past quarter-century occurred on opposing sides of the Southern
 77 Vanuatu Trench in 2021 and 2023. The resulting tsunamis of similar wave amplitude have distinct
 78 near-field patterns associated with the source location in relation to nearby seamounts and islands,
 79 but similar far-field patterns due to standing waves amongst the many seamounts and islands in

80 the southwest Pacific (Robert et al., 2025). This event pair within 2 years is analogous to the 2013
 81 Santa Cruz megathrust M_W 8.0 and 2015 normal faulting M_W 7.0 earthquakes on opposing sides of
 82 the trench in the northern Vanuatu subduction zone (Heidarzadeh et al., 2016). These recent
 83 earthquakes at the northern and southern termini of the subduction zone produced moderate
 84 tsunamis affecting Vanuatu and New Caledonia. Larger historical earthquakes between the two
 85 island chains, such as the 1875 M_W 8.1-8.2 and the 1995 M_W 7.7, indicate greater tsunami risk to
 86 population centers. Port Vila was extensively damaged by ground shaking from a nearby 54 km
 87 deep M_W 7.3 intraslab event in December 2024, accompanied by a minor tsunami of 0.25 m
 88 amplitude.

89 Governments, scientists, and stakeholders are motivated to understand earthquake and tsunami
 90 hazards to support comprehensive risk management strategies among nations in the Southwest
 91 Pacific. UNESCO-IOC (2025) proposed maximum earthquake scenarios inferred probabilistically
 92 from the estimated degree of segmentation, width of strain accumulation zones, fault locking
 93 relative to plate convergence, and material properties of rocks along the Vanuatu subduction zone.
 94 Comparable maximum earthquake estimates were made for the northern, central, southern, and
 95 Matthew-Hunter Islands regions along the arc. Full rupture of the southern 500-km long segment,
 96 where the proposed Tamtam SMART cable is located, can produce up to M_W 8.8 involving five
 97 M_W 8.33 subevents. These scenarios along with the well-resolved 2013 M_W 8.0 Santa Cruz Islands
 98 earthquake to the north and the 2021 and 2023 M_W 7.7 earthquakes southeast of the Loyalty Islands
 99 provide a range of large events in the region that the proposed SMART subsea cables might record
 100 signals for (Fig. 1b). Modeling the corresponding earthquake and tsunami signals can inform
 101 system and sensor design, aid data integration into regional networks, and identify implications
 102 for emergency management in the cable system planning stage.

103 **2. Tsunami and seismic wave modeling**

104 Finite fault-slip models have been an effective tool to describe earthquake rupture and seafloor
 105 deformation time histories for non-hydrostatic modeling of tsunami generation (Yamazaki et al.,
 106 2023). The methodology has evolved over the last half-century from simple point source models
 107 in homogenous, elastic half-space to space-time distributions of slip over a finite-fault surface or
 108 network of surfaces, constrained by combinations of seismic, geodetic, and tsunami observations.

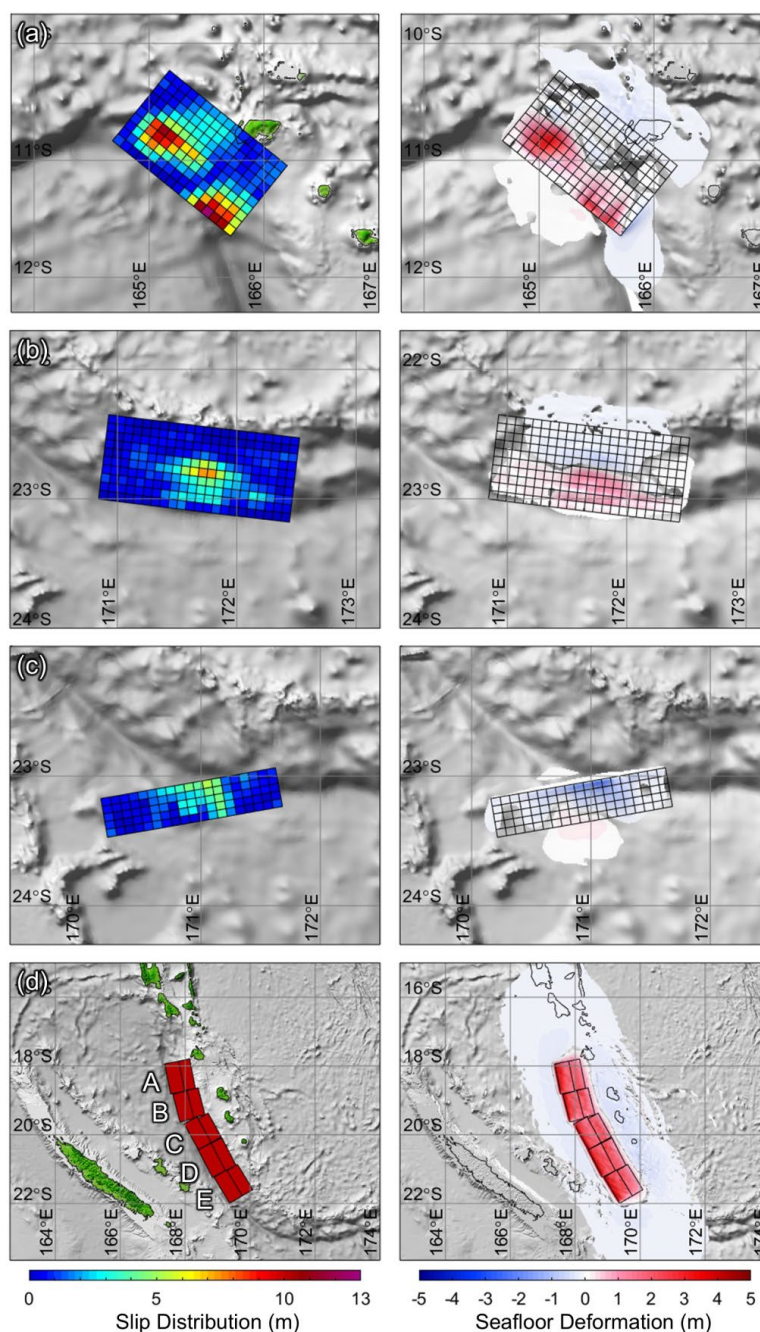

109 Such models are now routinely obtained for large earthquakes, and can be used in quantitative
 110 forward modeling of long-period ground motions at any location of interest.

111 **2.1 Rupture models**

112 Finite fault-slip models describe rupture kinematics through grids of subfaults, each of which
 113 has uniform slip and a parameterized source time function. The collective motion accounts for the
 114 spatial-temporal seismic moment and energy release during the rupture. In our present formulation,
 115 the seafloor vertical displacement is computed from the half-space solution of Okada (1985) and
 116 adjusted for horizontal translation of the local slope according to Tanioka and Satake (1996). Fig.
 117 2 shows the finite fault-slip models and co-seismic vertical seafloor displacement for the 2013 M_W
 118 8.0 Santa Cruz Islands earthquake (Lay et al., 2013), the 2021 and 2023 M_W 7.7 earthquakes
 119 southeast of the Loyalty Islands (Robert et al., 2025), and the M_W 8.8 maximum considered
 120 earthquake scenario for the southern Vanuatu subduction zone (UNESCO-IOC, 2025). The three
 121 historical events have finer subfaults that provide fairly detailed slip distributions and time
 122 histories inferred from global seismic and regional tsunami wave recordings, valid for seismic
 123 periods longer than ~ 5 -10 s. The maximum earthquake scenario has larger subfaults with
 124 prescribed uniform slip and rise time, and is only valid for seismic periods longer than ~ 15 s.

125 The 2013 M_W 8.0 Santa Cruz Islands earthquake has shallow eastward dip in two large slip
 126 patches and a southeastward rupture expansion at ~ 1.5 km/s. The megathrust rupture has up to
 127 12.7 m slip producing 3.3 m near-trench uplift and minor arc subsidence (Lay et al., 2013). The
 128 2021 M_W 7.7 thrust-faulting earthquake occurred at the plate boundary interface near the southern
 129 hook of the Vanuatu subduction zone. The peak slip reaches 7.5 m over a 55 s rupture time and
 130 produces 1.3 m uplift and minor subsidence on the lower and upper margin slope (Robert et al.,
 131 2025). The nearby 2023 M_W 7.7 earthquake with a similar east-west extent involved a normal fault
 132 in the outer rise. The peak slip reaches 5.2 m over a 45 s rupture time with relatively small uplift
 133 but large subsidence of 2.4 m near the trench (Robert et al., 2025). The finite fault models for the
 134 three historical events, which have been determined from joint seismic and tsunami modeling, are
 135 implemented to provide time histories of seafloor deformation for tsunami excitation directly.
 136 Short-period features of the sources and details of the propagation structures are not known, so we
 137 restrict our seismic modeling near the Tamtam sites to ground displacements with long-periods
 138 consistent with simplified, point-source model representations in a one-dimensional velocity
 139 structure.

140

141 **Figure 2.** Slip distribution and seafloor deformation. (a) The 2013 M_W 8.0 Santa Cruz Islands
 142 earthquake. (b) The 2021 M_W 7.7 earthquake southeast of the Loyalty Islands. (c) The 2023 M_W
 143 7.7 earthquake southeast of the Loyalty Islands. (d) UNESCO M_W 8.33 A, B, C, D, and E sub-
 144 events which combine to give the M_W 8.8 earthquake scenario.

145 The rupture of the maximum considered earthquake scenario extends 500 km along the
 146 southern Vanuatu subduction zone and 100 km downdip from the trench (UNESCO-IOC, 2025).
 147 The M_W 8.8 earthquake scenario corresponds to the 90th percentile in the posterior maximum
 148 moment distribution of the probabilistic tsunami hazard assessment compiled by Davis and Griffin
 149 (2018). The model has uniform slip of 10 m and a rigidity of 40 GPa. The slip is within the range
 150 of the three recent major events from 5.2 to 12.7 m, but is implemented over a much larger area
 151 for the maximum scenario. The uplift varies gradually from 1.1 m at the shelf edge to 4.6 m near
 152 the trench and the subsidence is relatively small due to the uniform slip across the full segment.
 153 The five M_W 8.33 subevents on 100 km wide and 100 km long ruptures can be considered
 154 separately as local failures along the segment to augment the parameter space. Each subevent is
 155 comparable to the largest observed, 1875 M_W 8.1-8.2 earthquake in the region (Ioualalen et al.,
 156 2017). For modeling of tsunami excitation, the rupture is assumed to start simultaneously across
 157 the entire fault and the dislocation follows a linear ramp function over a 30 sec rise time to reach
 158 the specified total slip. There is no known constraint on rupture heterogeneity or directivity.
 159 Simultaneous rupture of the five subevents is computed for the M_W 8.8 earthquake scenario to
 160 direct tsunami waves normal to the arc and to provide a conservative estimate of the resulting
 161 impact to local communities on either side.

162 **2.2 Tsunami modeling**

163 The tsunami code NEOWAVE augments the commonly used nonlinear shallow-water
 164 equations with depth-averaged vertical velocity and non-hydrostatic pressure (Yamazaki et al.,
 165 2009, 2011). The resulting quasi three-dimensional flow can describe tsunami generation from
 166 time-dependent seafloor deformation, frequency dispersion during trans-oceanic propagation, and
 167 wavenumber-dependent shoaling on seafloor slopes. The vertical inertia in the nonhydrostatic
 168 formulation facilitates accurate description of sea-surface oscillation at tsunami sources as well as
 169 runup and drawdown on steep topography (Bai et al., 2023). A shock-capturing scheme
 170 approximates breaking waves as bores or hydraulic jumps to ensure conservation of mass and
 171 momentum while enabling energy dissipation without predefined empirical mechanisms. These
 172 model capabilities have been benchmarked against mathematical and numerical models as well as
 173 laboratory and field measurements (Yamazaki et al., 2023).

174 The modeling involves two levels of two-way nested computational grids telescoping from the
 175 Southwest Pacific to the tsunami source region along the Vanuatu subduction zone. The digital

176 elevation model is derived from GEBCO14 at 30 arcsec (~ 0.9 km). The level-1 grid covers the
 177 Southwest Pacific to capture large-scale standing waves generated by reflection from land masses
 178 as well as trapping along island chains (Fig. 1a). The 2-arcmin (~ 3.7 km) resolution leads to
 179 optimal model dispersion for transoceanic tsunami propagation (Li and Cheung, 2019). As shown
 180 in Fig. 1b, the level-2 grid extends along the Vanuatu subduction zone and resolves the margin
 181 and tsunami sources at 30 arcsec (~ 0.9 km). The co-seismic seafloor vertical displacement defines
 182 the tsunami excitation and updates the digital elevation model. Inundation is not modeled at this
 183 resolution and the subgrid roughness of the seafloor is described by a Manning's number of 0.025.
 184 The local mean-sea level is the datum of the digital elevation model as well as the sea surface
 185 elevation.

186 **2.3 Seismic wave modeling**

187 Dynamic ground motions are computed at a target location (18.782°S , 168.2°E), which is
 188 planned for sensor 2 on the Tamtam SMART cable (Fig. 1b). The predicted ground motions vary
 189 slowly in space and thus remain very similar at the four sensor locations. The purpose here is to
 190 inform sensor design and data integration by estimating approximate timing, duration, and levels
 191 of long period ground displacement produced near the site for large recent plate boundary and
 192 plausible maximum regional ruptures along the Vanuatu subduction zone. The precise details of
 193 the historical, finite-fault ruptures are not important here and are unknown for maximum rupture
 194 scenarios. Numerical modeling is thus simplified to computation of equivalent point-source
 195 representations of the three large recent events and the subevents of the maximum rupture scenario
 196 along with their composite.

197 Synthetic seismograms are computed using a standard one-dimensional Earth Model, which is
 198 an anisotropic version of the Preliminary Reference Earth Model (PREM; Dziewonski and
 199 Anderson, 1981). The ground displacements up to 2 s period are computed using the SYNGINE
 200 (synthetic engine) seismic wave simulator (<https://ds.iris.edu/ds/products/ondemandsynthetics/>),
 201 for point-source moment tensor representations of the earthquake models. While short-period
 202 seismic waves and associated ground velocities and accelerations will be affected by the actual
 203 three-dimensional structure along the paths from sources to the observing location, the details are
 204 not known for this particular assessment of the ground shaking levels. Our focus is on the relative
 205 timing, duration, and amplitude of long period ground displacements produced by each source near
 206 the Tamtam site.

207 **3. Model results**

208 The modeling work provides tsunami and seismic waves generated by the three recent major
 209 earthquakes and the UNESCO maximum scenario including its five subevents along the Vanuatu
 210 subduction zone. The tsunami modeling covers an elapsed time of 10 hours to capture shelf
 211 oscillations along the archipelago as well as standing waves within the north and south Fiji Basins.
 212 The results include regional tsunami amplitude maps, energetic oscillation modes along the
 213 margin, and synthetic tsunami and seismic waveforms at the representative, sensor 2 location of
 214 the planned SMART subsea cable.

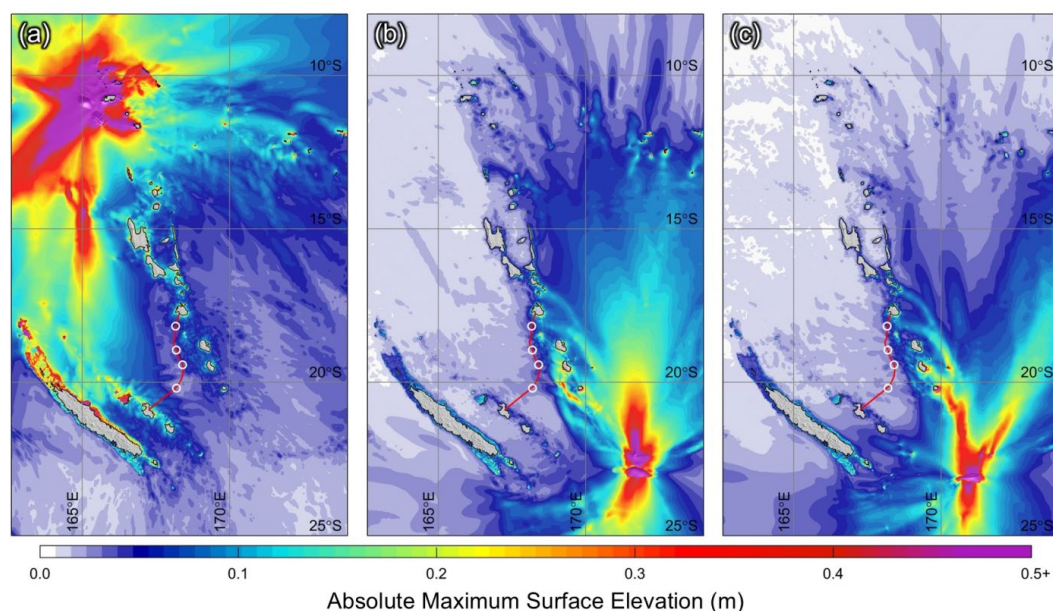

215 **3.1 Recent major events**

216 The 2013 M_W 8.0 Santa Cruz Islands earthquake and the 2021 and 2023 M_W 7.7 earthquakes
 217 southeast of the Loyalty Islands are representative of major events from the northern and southern
 218 termini of the Vanuatu subduction zone. Fig. 3 shows regional distributions of the maximum sea
 219 surface excursion, which includes crest and trough amplitude to better represent the energy pattern,
 220 especially for the 2023 normal-fault event (Robert et al., 2025). The two near-trench uplift patches
 221 from the 2013 thrust faulting provide the primary source of the tsunami with minor contributions
 222 from subsidence on the upper margin slope (Fig. 2a). Constructive interference of the radiated
 223 waves from the two uplift patches defines the main lobes in the northeast and southwest directions
 224 away from Vanuatu (Fig. 3a). Refraction of the radiated waves over the margin slope and outer
 225 rise produces notable side lobes to the east and south toward the Santa Cruz Islands and the main
 226 island of New Caledonia, respectively. The SMART cable site located southeast of the source on
 227 the margin slope experience only minor wave action albeit with amplification over adjacent insular
 228 shelves along the Vanuatu Islands.

229 The 2021 and 2023 M_W 7.7 earthquakes on opposing sides of the southern Vanuatu Trench
 230 have similar east-west rupture extents, but produce tsunamis with a leading crest and a leading
 231 trough associated with the thrust and normal faulting mechanisms, respectively (Robert et al.,
 232 2025). The distinct northern energy lobes result from the source location relative to seamounts and
 233 islands immediately north along the Hunter Ridge. In comparison, the southern lobes are normal
 234 to the strike of the respective earthquakes due to lack of major bathymetric features south of the
 235 source. The 2023 earthquake has narrower seafloor deformation beneath deeper water resulting in
 236 shorter period tsunami waves that are focused more effectively along seamounts and island chains
 237 to produce a more elaborate wave pattern. Both tsunamis generated by earthquakes in the southern

238 arc of the subduction zone direct the primary energy to the north and south with minimal threat to
 239 the main island of New Caledonia. Refraction of the radiated waves over the margin slope
 240 generates side lobes toward the Vanuatu Islands with moderate wave action associated with shelf
 241 oscillations for both events.

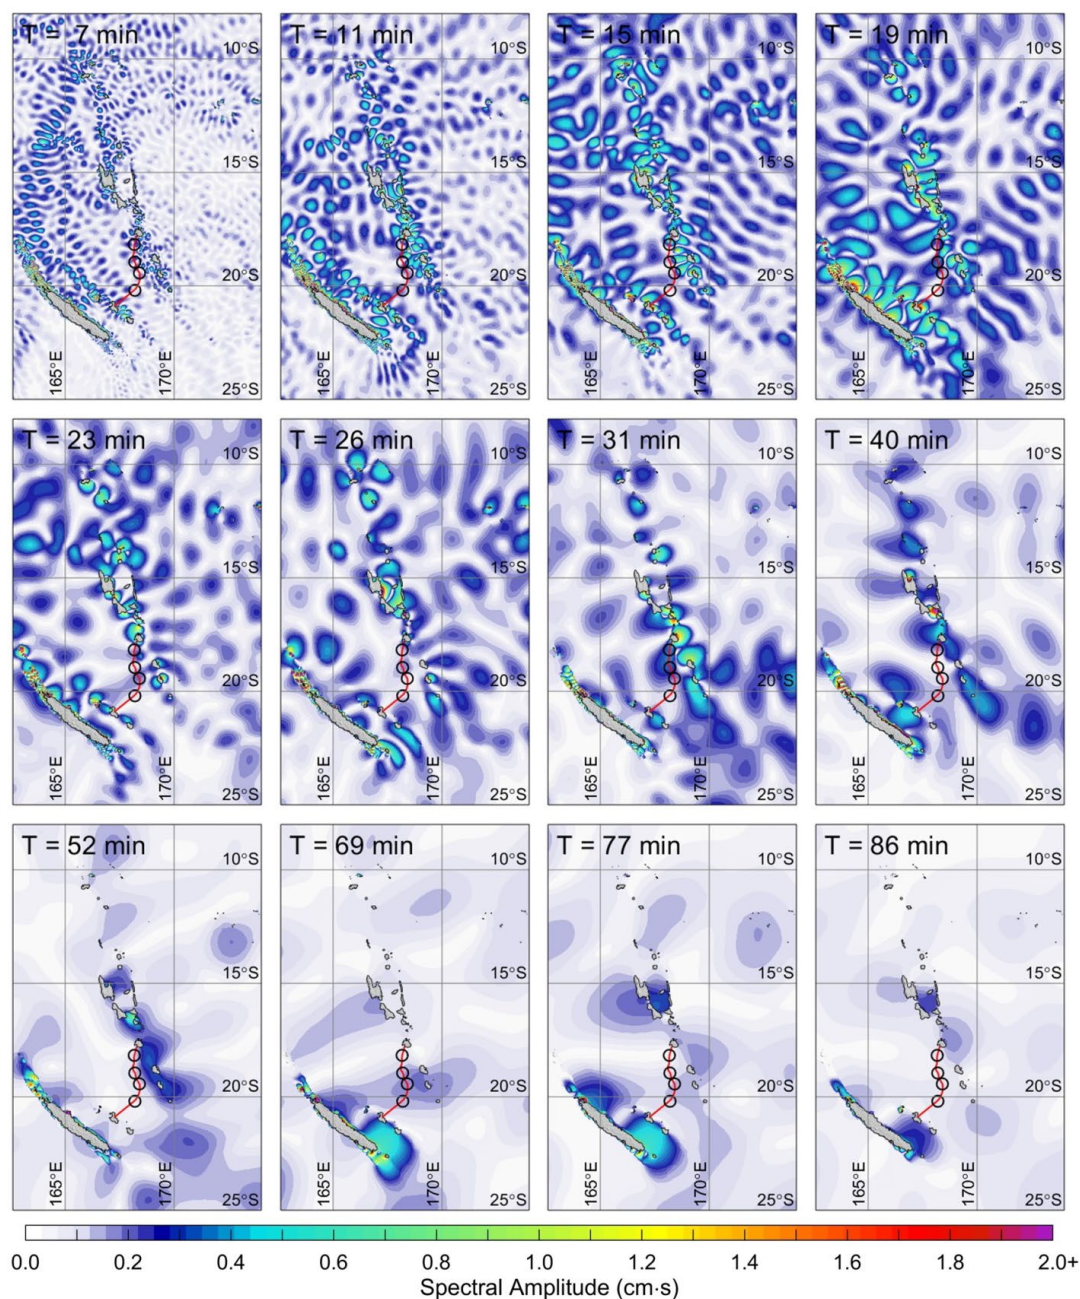

242
 243 **Figure 3.** Computed absolute maximum surface elevation of tsunamis generated by recent major
 244 earthquakes. (a) The 2013 M_W 8.0 Santa Cruz Islands earthquake. (b) The 2021 M_W 7.7 Southeast
 245 of Loyalty Islands earthquake. (c) The 2023 M_W 7.7 Southeast of Loyalty Islands earthquake. Red
 246 line and circles denote planned SMART cable and sensor locations.

247 The four planned sensor modules are located off the insular shelves (Fig. 1b) and outside zones
 248 of tsunami amplification for all three recent events (Fig. 3). The computed sea-surface elevations
 249 at the sensors are an order of magnitude smaller compared to the adjacent shallow shelves. The
 250 bathymetry-driven oscillation is illustrated by spectral analysis of the computed 2013 tsunami that
 251 converts the surface elevation time history to amplitude as a function of period (Munger and
 252 Cheung, 2008). Fig. 4 shows selected oscillation modes with well-defined nodal lines, where the
 253 amplitude is zero and the phase varies by 180° across indicative of resonance. The 7 to 40-min
 254 modes indicate distinct standing edge waves along the New Caledonia ridge, the Loyalty Island
 255 ridge, and the Santa Cruz and Vanuatu Islands. The standing waves along the geographically
 256 smaller, Loyalty Island ridge vanish for longer-period oscillations at margin and basin scales. Since
 257 the oscillation modes are independent of tsunami sources (e.g., Cheung et al., 2013; Aranguiz et

258 al., 2019), the SMART sensors located mostly outside energetic antinodes can record direct
 259 tsunami signals with minor influences from adjacent landmasses.

260
 261 **Figure 4.** Oscillation modes derived from the 2013 M_W 8.0 Santa Cruz tsunami. Red line and
 262 circles denote planned SMART cable and sensor locations.

Fig. 5 shows the computed waveforms and spectra from the 2013, 2021, and 2023 tsunamis at sensor 2. All three tsunamis arrive in ~ 1 hr after earthquake initiation. The 2013 and 2021 thrust faulting events produce initial arrivals in the form of a crest, while the 2023 normal faulting results in a leading trough. The initial arrivals directly from the source via the Vanuatu trench are weak for the 2021 and 2023 events southwest of the Loyalty Islands, because the energy is diverted into the North Fiji Basin through refraction-diffraction across the Hunter Ridge (Robert et al., 2025). The subsequent waveforms are primarily leaked energy from nearby shelf oscillations, where the amplitude is an order of magnitude larger (Fig. 3). The 2013 tsunami from the San Cruz Islands has more energetic long period components due to the sensor's location at 90° azimuth from the main lobe. Despite the varying waveforms in the three events, their spectra show similar sets of harmonics with periods in 10–40 and 50–100 min associated with the island and basin-scale oscillations as shown in Fig 4.

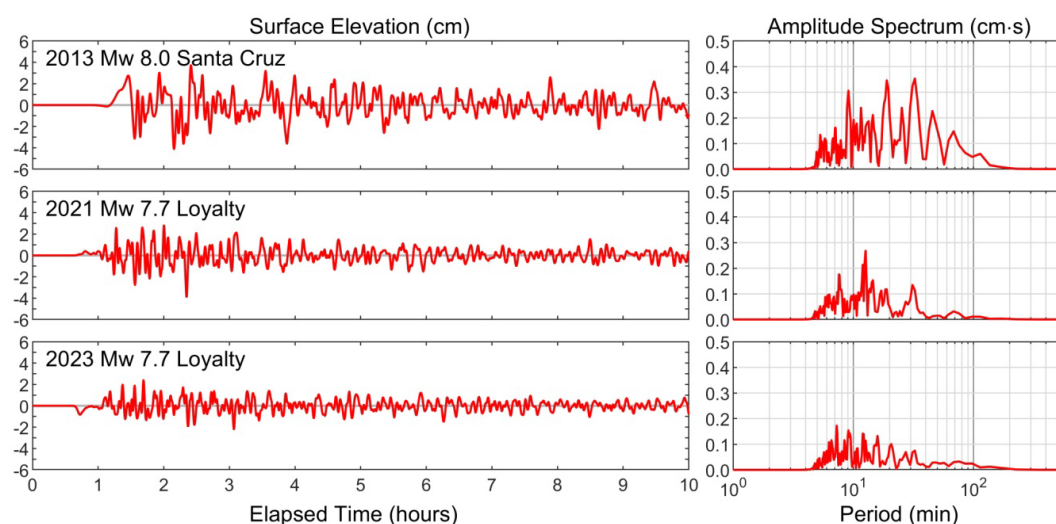

Figure 5. Synthetic tsunami time series and spectra at the target location of SMART sensor 2 from the three recent major earthquakes in the Vanuatu subduction zone shown in Fig. 2a-c.

The vertical and transverse (horizontal perpendicular to the great circle path at the receiver) ground displacements at sensor 2 of the SMART cable are computed for point-source representations of the three major recent ruptures along the Vanuatu subduction zone (Fig. 6). A 15-s low-pass filter has been applied to approximately account for temporal finiteness of the ruptures. The arrival times vary with distance from the source to the observing point. Peak ground motions of about 0.2 m are associated with the large Rayleigh wave and Love wave packets on the

284 vertical and transverse components, respectively. The signals include all body wave arrivals. The
 285 initial P wave arrives at about 75-120 s after the origin time, when real-time analysis of ground
 286 shaking detected at the cable could commence. With a distribution of 4 three-component sensors
 287 along the cable, if on-scale recordings are obtained, rapid array processing could determine the
 288 azimuth of approach, and initial ground motion amplitudes can be used for magnitude estimation.
 289 Surface wave analysis of the larger signals is viable within 150 to 380 s of the earthquake origin
 290 time, if low frequency signals are recorded. With tsunami arrivals also varying with source
 291 distance, rapid tsunami potential assessment could be commenced using the Tamtam cable
 292 observations along with regional and global network observations.

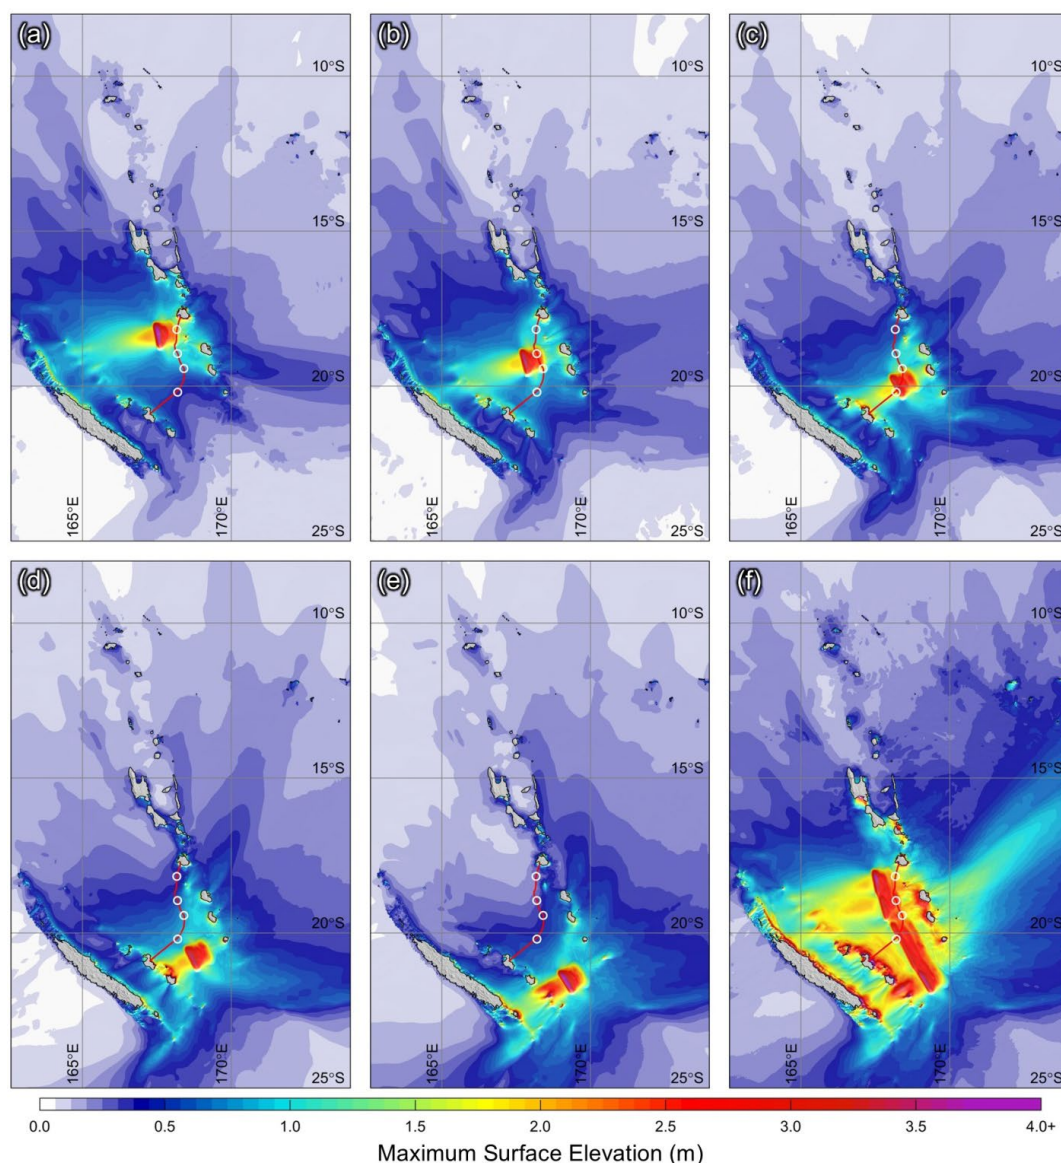

293
 294 **Figure 6.** Synthetic ground displacement time series at the target location of SMART sensor 2
 295 from three recent major earthquakes in the Vanuatu subduction zone shown in Fig. 2a-c.

296 3.2 UNESCO scenarios

297 The UNESCO M_W 8.8 maximum earthquake scenario and its five M_W 8.33 subevents
 298 complement the historical events to provide more complete coverage of the parameter space,
 299 especially along the most critical southern segment adjacent to population centers. Fig. 7 shows
 300 the tsunami wave amplitude along the Vanuatu subduction zone for the six scenarios. The initial
 301 wave of the thrust-faulting events is characterized by sea-surface uplift across the margin slope
 302 reaching 3.7 m near the trench. Subevent A at the northern end of the segment has the most severe
 303 impact to Vanuatu with waves reaching 8.5 m elevation at the east-facing shore of Efate Island,
 304 while subevents to the south are more critical to the Loyalty Islands with a maximum elevation of
 305 9.3 m at Maré Island (Fig. 7). For the combined M_W 8.8 scenario, the arc curvature focuses the
 306 energy toward the southern Vanuatu Islands with nearshore amplification to 11.5 m elevation at

307 Tanna Island. The computed water elevation reaches 12.7 and 11.9 m at Lifou Island and the main
 308 island of New Caledonia. Since these values are surface elevations at the shore resolvable by the
 309 0.5 arcmin (0.9 km) grid, runup heights might be larger or smaller depending on the coastal terrain.

310
 311 **Figure 7.** Computed wave amplitude of tsunamis generated by UNESCO earthquake scenarios in
 312 Figure 2d. (a) M_W 8.33 A earthquake. (b) M_W 8.33 B earthquake. (c) M_W 8.33 C earthquake. (d)
 313 M_W 8.33 D earthquake. (e) M_W 8.33 E earthquake. (f) M_W 8.8 combined maximum earthquake
 314 scenario. Red line and circles denote planned locations of the SMART cable and sensors.

At least one SMART sensor will be located within the tsunami source regions of subevents A through C as well as the combined event with immediate signature of the initial sea surface uplift. An analysis of the model data shows travel times of 11 and 18 min for the tsunamis sourced from subevents D and E to reach the nearest sensor. Fig. 8 shows the computed waveforms and spectra at sensor 2 from the five subevents and the combined scenario for illustration. The sea surface rises to 2.5 m during the rupture of subevent B directly beneath the sensor, and with only minor energy trapping or resonance over the margin slope, the oscillation subsides rapidly through radiation. Even with rapid wave attenuation outside the source region, the sensor registers direct tsunami signals with less than 1 m amplitude for the other subevents. The combined event has initial wave amplitude similar to subevent B, but the much larger rupture length results in stronger codas due to waves arriving sequentially from the five subevents along the segment. The wave spectra for all six scenarios show strong bimodal, island and basin-scale excitations with peaks closely aligned with the oscillation modes deduced from the 2013 Santa Cruz Island event (Fig. 4).

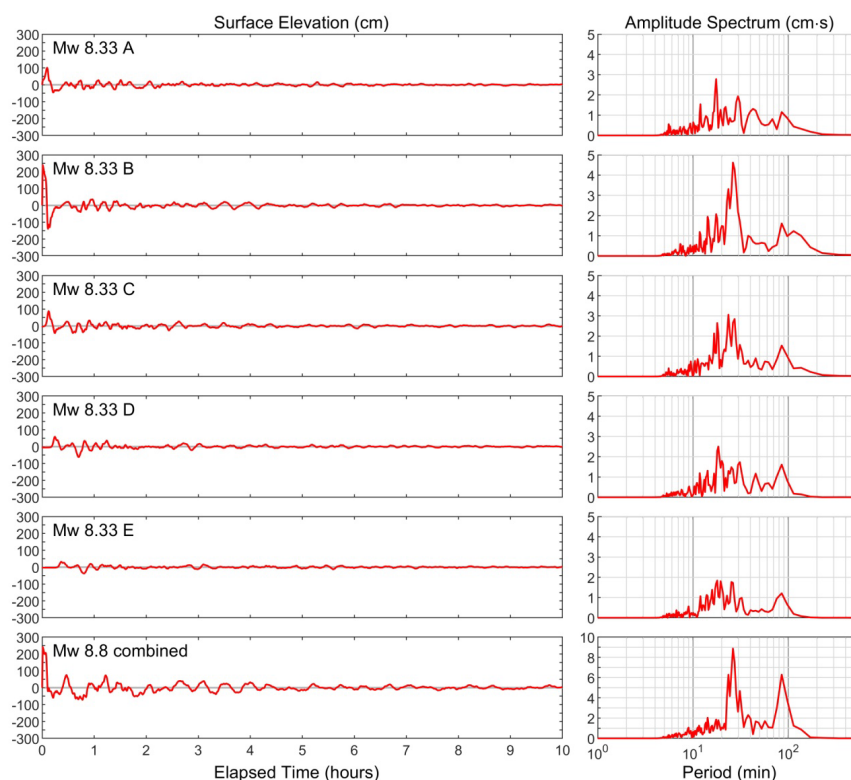

Figure 8. Synthetic tsunami time series and spectral at the target location of SMART sensor 2 for the UNESCO earthquake scenarios shown in Fig. 2d.

331 The seismic waves at the sensor 2 location are computed for the individual M_W 8.33 subevents
 332 and the M_W 8.8 combined faulting. All scenarios involve 10 m slip with moment tensor point
 333 sources at subevent centers and synchronous rupture of the entire segment for simplicity. Fig. 9
 334 shows the subevent signals comprising complete seismic ground motions as well as static
 335 displacements. A low-pass filter with a 15 s corner has been applied to approximately account for
 336 the expected smoothing over the subevent space-time extent. Ground motions are shown for the
 337 vertical and transverse components and the time variations between arrivals indicate the distance
 338 from subevent centers to the sensor. The strongest seismic waves are produced by subevent B
 339 directly beneath the sensor with peak vertical and transverse transient displacements reaching 7 m
 340 as well as a static transverse displacement of ~ 1 m after passage of the large surface waves.

341
 342 **Figure 9.** Synthetic ground displacement time series at the target location of SMART sensor 2 for
 343 the UNESCO M_W 8.33 earthquake scenarios A-E in Fig. 2d. A point-source at the center of each
 344 subfault is used for the calculations, and the displacements are low-pass filtered at 15 s period to
 345 account for slip duration over the subevent. Vertical and transverse (orthogonal to the great-circle
 346 connecting the source and sensor locations) ground displacements are shown.

347 The composite, long duration displacement for the M_W 8.8 earthquake scenario is shown in
 348 Fig. 10. Since the subevents are assumed to rupture at the same time, their arrivals are delayed by
 349 propagation distance alone. The composite ground motions are expressed in terms of the vertical,
 350 north-south, and east-west components because the transverse component changes with each
 351 subevent location. A 15-s low-pass filter is again applied to approximately account for finiteness
 352 of the individual subevents. The sequence of discrete subevent pulses would be smeared out for a
 353 true continuous rupture, but the heterogeneous coupling expected along the subduction zone would
 354 likely involve correspondingly complex localized failures. The peak ground motion is about 6 m

on the vertical and 7.5 m on the horizontal components along with appreciable static displacements due to the sensor location in the rupture zone.

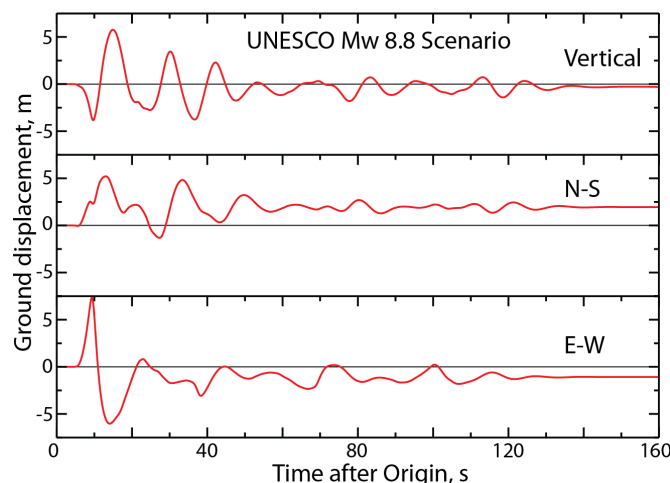

Figure 10. Synthetic ground displacement time series at the target location of SMART sensor 2 for the UNESCO M_W 8.8 earthquake scenario in Fig. 2d. For simplicity, the 5 subevents are assumed to rupture synchronously, and the summed displacements are shown for the vertical, north-south, and east-west components of motion due to the changing geometry relative to the target location. A low pass filter at 15 s has been applied.

4. Discussion and Conclusions

Large earthquakes occur along the entire Vanuatu subduction zone exposing many islands in the region to strong ground shaking and tsunami wave impact. Prior studies have systematically examined the hazards and developed fault models for recent major earthquakes and maximum events. These fault models form a basis to develop a plausible range of seismic and tsunami waveforms expected at the Tamtam SMART cable. The results provide a reference for hazard assessment, system and data integration, and emergency management.

4.1 Earthquake and tsunami hazards

There have been 18 shallow (< 70 km deep) M_W 7.5+ earthquakes recorded in the Vanuatu subduction zone since 1900 (Cleveland et al., 2014; UNESCO-IOC, 2025). The UNESCO maximum scenario of M_W 8.8 provides an upper-bound estimate of potential ground motions and tsunami impacts, but a far-smaller, more frequent major event in the southern segment can still devastate local communities in Vanuatu and New Caledonia. For example, the tsunami generated by the 1875 M_W 8.1-8.2 earthquake produced sediment deposits reaching 10 m elevation on the

northeastern coast of Lifou Island, New Caledonia (Paris et al., 2023). The impact is comparable to the UNESCO subevents of M_W 8.33 with computed sea-surface elevation reaching 8.5 and 9.3 m at the shore of Efate Island and Maré Island in Vanuatu and New Caledonia. A recent 17 December 2024 M_W 7.3 earthquake located 24 km west of Port Vila took 14 lives and injured 265, producing extensive damage in the capital of Vanuatu and long-term impacts on the tourism industry (World Bank, 2025). This event was 54 km deep within the subducting slab, but still produced a 25 cm tsunami. The depth and proximity of such an event to the island leaves little warning times for seismic or tsunami wave arrivals either with or without the Tamtam cable.

A major event from the northern or Matthew-Hunter segment, such as the 2013 M_W 8.0 and 2021 and 2023 M_W 7.7 ruptures, also poses earthquake and tsunami hazards in Vanuatu and New Caledonia. The resulting tsunami arrives at the cable locations within an hour after the earthquake allowing limited time to respond if deemed destructive. Hazardous ocean conditions can be long lasting due to amplification and trapping of tsunami energy along island chains (Cheung et al., 2013). The resulting surges might damage ships and disrupt harbor operations despite having minor inundation risks. The limited number of regional seismic and geodetic sensors in operation hampers earthquake and tsunami warning capabilities along the entire subduction zone. The deployment of continuous monitoring along the Tamtam cable may contribute substantially to regional event detection and rapid assessment, particularly along the southern Vanuatu subduction zone.

4.2 Sensor system and data

The seismic, pressure, and temperature sensors are installed inside the repeater housing or in separate modules of submarine telecommunication cables in the case of Tamtam. The broadband seismic sensors and optional accelerometers will be provided by Nanometrics (<https://nanometrics.ca>), and the temperature and pressure sensors will be supplied by RBR (<https://rbr-global.com>). The fabrication of sensor modules will be integrated into the cable manufacturing process by Alcatel Submarine Networks (ASN) through its Climate Change Nodes initiative. The collected data from the Tamtam SMART cable will be provided via ASN's Climate Change Portal for low-latency distribution to hazards monitoring agencies, such as the Vanuatu Meteorological and Geohazards Department (VMGD), Oceania Regional Seismic Network (ORSNET), and for long-term storage and dissemination for further analysis and climate research via Ifremer (French Research Institute for Exploitation of the Sea).

408 With tsunami waves arriving well after seismic waves, rapid tsunami potential assessment
409 could be commenced using the cable seismic observations along with regional and global land-
410 based seismic network records. The spectral analysis has shown recorded tsunamis signals from
411 sensors placed outside insular shelves have minor effects from resonance oscillations to provide
412 general indications of potential impact and confirm inferences from seismic observations. Caution
413 must be exercised for earthquake sources near the sensors. Large dynamic ground displacement
414 might interfere with operations of motion sensors laid on sediments. Lacking specific knowledge
415 of the short-period ground displacements and the associated ground velocities and accelerations,
416 we do not attempt to predict the actual recording fidelity of the Tamtam sensors, but after
417 deployment, ground motion models can quickly be developed for the paths around the stations.
418 Also not considered in this study is seismic noise in water level records that might mask initial
419 tsunami arrivals as commonly seen in bottom pressure data from DART stations near earthquake
420 sources (e.g., Bai et al., 2022, 2023). Additional QA/QC and post-processing are warranted as part
421 of automated data analysis (e.g., An et al., 2017).

422 **4.3 Emergency management**

423 Vanuatu is an island nation in the Southwest Pacific with an 800-900 km long archipelago of
424 83 islands. The Vanuatu Meteorology and Geohazards Department (VMGD) is the government
425 institute with the mandate to monitor meteorological and geological hazards, including volcanoes,
426 earthquakes, and tsunamis, and provide early warning updates to the public. VMGD has an
427 established geological monitoring network consisting of 15 plus seismic monitoring stations
428 scattered along the six provinces of Vanuatu. Broadband sensors and established telemetry
429 transmission to the VMGD data center enables near real time seismic event detection. The
430 installation of tide gauges near the coastline of some islands assists with tsunami monitoring.
431 However, the detection range is localized to Vanuatu region and does not extend regionally or to
432 the subduction zone.

433 The National Disaster Management Office (NDMO) is responsible for the response and
434 recovery to any disaster and activation of the National Emergency Operations Center with the
435 advice from VMGD. Having a well-established hierarchy of groups down to province and
436 community levels allows coordinated pre-disaster awareness and outreach efforts and transfer of
437 response and recovery efforts to the government and partners post disaster. The effectiveness of
438 preparedness and mitigation measures developed is a result of the availability of the real-time

439 seismic and historical data possessed by VMGD. The latter is now augmented here by synthetic
440 seismic and tsunami data from three recent major earthquakes and tsunamis as well as the
441 UNESCO-IOC maximum scenario along with its subevents for hazard assessment and long-term
442 planning.

443 The deployment of the Tamtam SMART cable and integration of its real-time data into
444 VMGD's monitoring system will greatly enhance the current early warning system. The Vanuatu
445 subduction zone has so far been lacking direct observation since there has never been monitoring
446 equipment installed in the area. The seismic, temperature and pressure data that will be made
447 available by the four proposed ASN Climate Change Nodes will feed additional information to the
448 current system providing earthquake detection parameters and tsunami threat analysis in and
449 around the subduction zone. Acquiring such data will support preparedness and mitigation efforts
450 developed by NDMO resulting in a well informed and prepared country. The benefits will extend
451 to the southwest Pacific and will be of great interest to the research community as well.

452 *Code availability.* The NEOWAVE code for tsunami modeling may be requested from the
453 corresponding author for academic research. The SYNGINE seismic wave simulator is available
454 online (<https://ds.iris.edu/ds/products/ondemandsynthetics/>).

455 *Data availability.* The digital elevation model used in this study is available at GEBCO
456 (https://www.gebco.net/data_and_products/gridded_bathymetry_data/).

457 *Authorship contribution.* KC: Conceptualization, Methodology, Investigation, Project
458 Administration, Writing - original draft, review and editing. YY: Methodology, Investigation,
