**Abstract.** Soil is a large pool of carbon (C), storing globally twice as much carbon as the atmosphere and three times as much as vegetation. Soil organic carbon (SOC) stocks are significantly impacted by land-use changes, either negatively when forests or grasslands are converted into crops or positively when the opposite occurs. This context underpins the “4per1000” initiative, which aims to promote SOC storage in soils as a mitigation strategy. However, intensive cropping and climate change may lead to losses of organic and inorganic carbon from soils, which calls for long-term observations of soil organic carbon stocks in reference ecosystems worldwide. To address this, a harmonised reference soil sampling protocol was developed for all ecosystem sites within the European Integrated Carbon Observing System (ICOS) research infrastructure, starting in 2017 with revisits planned every 5–10 years. This study presents a first case at the French cropland site FR-Gri (wheat–maize–barley–oilseed rape rotation), assessing SOC stock in 2019 with the ICOS protocol, which was combined with earlier SOC stock sampling data from the European project CarboEurope. A significant soil decompaction was observed over the 13.5 years in the 0-30 cm layer. Bulk density decreased by 22% in the 0-5 cm layer (from 1.31 to 1.02 g cm<sup>-3</sup>) and by 5% in the 5-30 cm layer (from 1.53 to 1.45 g cm<sup>-3</sup>), likely due to the adoption of reduced tillage since 2004. SOC content increased by 10% in the 0-5 cm layer but declined by 6.2% in the 5-30 cm layer. The SOC stocks based on equivalent soil mass (ESM) increased by 7.6% in the 0-5 cm layer, but decreased by 11% and 9% in the 5-30 cm and 30-60 cm layers, respectively. Overall, the ESM-based SOC stock in the 0-60 cm layer decreased by approximately 0.95 ± 0.22 kg C m<sup>-2</sup> (or 9 Mg C ha<sup>-1</sup>) between 2005 and 2019, corresponding to 0.65% yr<sup>-1</sup> relative to the initial SOC stock (~11 kg C m<sup>-2</sup> in the 0–60 cm layer). This leads to an average yearly decrease rate of 0.072 ± 0.017 kg C m<sup>-2</sup> yr<sup>-1</sup> (or 0.72 ± 0.17 Mg C ha<sup>-1</sup> yr<sup>-1</sup>), consistent with previous studies. To further interpret this trend, we applied the soil carbon cycling model AMG to simulate soil carbon dynamics down to a 30 cm depth from 2005 onwards. Based on site-specific exports and imports and estimated residue returns, the model predicted a SOC stock decline larger than the observed one in the 0-30 cm depth, stabilising around 2028, assuming management stays the same in the future. By 2040, SOC stocks are projected to decline to 6.9 kg C m<sup>-2</sup>, representing an approximate 15% reduction from the 2005 baseline. Furthermore, the AMG simulation was also consistent with the carbon flux balance reported by Loubet et al. (2011) for the period between 2006 and 2010. The observed

41 decrease in SOC stocks may be attributed to a shift towards larger exports, lower residue returns, and reduced  
42 carbon imports at this site compared to past management practices. This study highlights the importance of high-  
43 quality SOC stock change monitoring, as developed within the ICOS research infrastructure.

## 44 **1 Introduction**

45 Soil is one of the largest reservoirs of carbon (C) and nitrogen (N) in the terrestrial biosphere. Globally, soils store  
46 approximately 1500- 2400 Gt of organic C (SOC) in the upper meter (Batjes, 1996; Sanderman et al., 2017) and a  
47 comparable amount as inorganic C to a depth of 2 m (Zamanian et al., 2021), far exceeding the carbon stored in  
48 the atmosphere and vegetation combined (Antón et al., 2021). Hence, minor changes in SOC stocks can have  
49 substantial impacts on atmospheric carbon dioxide (CO<sub>2</sub>) concentrations and climate feedbacks (Minasny et al.,  
50 2017).

51 Agricultural management is a major driver of SOC dynamics through its control of organic matter inputs, soil  
52 disturbance, and residue incorporation, in interaction with climate and soil properties (Paustian et al., 2016). In-  
53 tensive farming practices, such as simplified crop rotations, frequent tillage, and high fertiliser use, have commonly  
54 been associated with SOC losses by accelerating organic matter decomposition and reducing C inputs to soils  
55 (Autret et al., 2016; Schmidt et al., 2011; Six et al., 2002). Conversely, management practices that enhance C  
56 inputs (mineral fertilisation, diversified crop rotation, cover crops, organic amendments) and reduce soil disturb-  
57 ance (reduced-tillage and no-tillage) have been shown to promote SOC accumulation or slow SOC losses (Lal,  
58 2004; Poeplau and Don, 2015; Schmidt et al., 2011). Based on a review of practices, it has been hypothesised that  
59 generalising C-storing practices could increase C sequestration in the upper metre of agricultural soils by 2 to 3  
60 Pg C yr<sup>-1</sup>, which roughly corresponds to 4 per 1000 per year of the current C stock (Minasny et al., 2017). How-  
61 ever, such estimates remain highly uncertain and variable in space, while major concerns remain on the persistence  
62 of soil carbon gains over time as soils approach a new equilibrium (Baveye et al., 2018; Franzluebbers et al., 2012).  
63 In Europe, current bottom-up inventories show croplands as a net C source of  $10 \pm 9 \text{ g C m}^{-2} \text{ yr}^{-1}$ , whereas grass-  
64 lands and forests act as net C sinks of  $57 \pm 34 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $20 \pm 12 \text{ g C m}^{-2} \text{ yr}^{-1}$ , respectively (Schrumpf et al.,  
65 2011; Schulze et al., 2009). However, top-down estimates of terrestrial C budgets indicate that European terrestrial  
66 ecosystems are an overall sink of approximately  $-100 \text{ Tg C yr}^{-1}$ , but with considerable associated uncertainties of  
67  $\pm 360 \text{ Tg C yr}^{-1}$  (Petrescu et al., 2021). Accurately quantifying temporal changes in SOC stocks remains a signifi-  
68 cant source of uncertainty in terrestrial carbon budgets.

69 Reliable monitoring of SOC stocks requires accurate quantification of the bulk density (BD), the fine earth fraction  
70 (FE, the fraction of soil below 2 mm), and the carbon content, throughout the soil profile (Molteni and Corti, 1998),  
71 as well as a sufficiently dense sampling design to reduce uncertainty associated with spatial variability (Batjes,  
72 1996). Bulk density measurements are often complex and time-consuming, particularly in rocky soils, and are  
73 therefore frequently estimated using pedotransfer functions (PTFs). However, the use of PTF-derived BD can  
74 introduce systematic bias, particularly when rock fragments (RF) are inadequately accounted for, or when circular  
75 predictors such as SOC content are used (Schrumpf et al., 2011; Xu et al., 2015). But bulk density can substantially  
76 vary over decades, in response to management practices, soil compaction and decompaction, erosion, and climate-  
77 driven soil processes such as wetting–drying cycles, freeze–thaw dynamics, and shrink–swell behaviour of clay  
78 soils (Hopkins et al., 2009). Because BD directly determines soil mass, such variations critically affect estimates  
79 of SOC stock over time.

80 To address this issue, Ellert and Bettany (1995) proposed the equivalent soil mass (ESM) method as an alternative  
81 to the fixed depth (FD) method for measuring SOC stock changes. In the FD method, SOC stock changes are  
82 evaluated at constant soil depths and can induce significant biases when BD varies over time (Beem-Miller et al.,  
83 2016). In the ESM approach, SOC stocks are evaluated for a constant soil mass per unit area, thereby compensating  
84 for changes in BD by adjusting the soil depth accordingly (Ellert and Bettany, 1995; von Haden et al., 2020;  
85 VandenBygaert and Angers, 2006; Wendt and Hauser, 2013). Differences between FD and ESM can account for  
86 up to 10% of SOC changes and may overwhelm variations caused by tillage and crop residue removal rates (Du  
87 et al., 2017; Xiao et al., 2020). As comparing SOC stocks on the same soil mass per unit area is recognised as a  
88 better practice than the FD approach, this methodology was included as the reference method by FAO and IPCC  
89 (FAO, 2019; IPCC, 2019).

90 Soil organic C stocks are key estimates within the Integrated Carbon Observation System (ICOS), a European  
91 Research Infrastructure Consortium (Heiskanen et al., 2022). As of 2025, ICOS includes 45 high-quality and  
92 standardised ecosystem sites (Class 1 and 2 stations), covering the diversity of European soils and ecosystems.  
93 Within ICOS, SOC stocks have been measured since 2017 and will be re-measured every 10 years to quantify  
94 changes in SOC stock over time. To ensure unbiased and robust estimates with a limited number of samples (Ar-  
95 rouays et al., 2018; Don et al., 2007; Saby et al., 2008), ICOS adopts a Design-Based (DB) approach (Brown,  
96 1992; Collins, 1992) with randomly selected sampling points (Arrouays et al., 2018; Brus and deGruijter, 1997;  
97 de Gruijter et al., 2006; Loustau et al., 2017). At each ICOS site, the measured soil stock change over time can  
98 then be compared to the integrated CO<sub>2</sub> fluxes at the site boundaries over that period, which comprise the net  
99 ecosystem productivity, imports to and exports from the site, and lixiviated fluxes (Aubinet et al., 2009; Ceschia  
100 et al., 2010; Loubet et al., 2011). Soil carbon cycling models such as DAYCENT (Parton et al., 1998), STICS  
101 (Brisson et al., 1998), RothC (Coleman and Jenkinson, 1996), or AMG (Clivot et al., 2019) are essential tools to  
102 further understand the observed SOC dynamics based on site-specific managements, and in particular exports,  
103 imports, and residue returns. Models are also key in providing long-term simulation of SOC stock dynamics and  
104 scenario analysis.

105 Given the 10-year resampling interval, evaluations of SOC stock changes, entirely based on the ICOS protocol,  
106 will only become available starting in 2027. However, before ICOS, several European sites were sampled from  
107 2005 to 2010 using a systematic grid-based sampling design within the EU CarboEurope project (Schrumpf et al.,  
108 2011), providing a unique opportunity to assess SOC stock changes, while explicitly addressing methodological  
109 challenges related to sampling design, bulk density variability, and SOC stock calculation approaches. At the Gri-  
110 gnon ICOS ecosystem station (FR-Gri), a cropland site, SOC stock was measured in 2005 using a grid-based  
111 design and later in 2019, using the ICOS protocol. The objectives of this study are to (1) quantify SOC stock  
112 change between 2005 and 2019 at the FR-Gri station, (2) compare SOC stock changes estimates obtained using  
113 the equivalent soil mass and fixed depth approaches, (3) discuss the uncertainties related to these estimations,  
114 mainly those related to sampling design, and (4) compare the observed SOC stock changes with predictions from  
115 the AMG soil carbon model (Clivot et al., 2019) and with previously established carbon flux balance estimations  
116 at the same site by Loubet et al. (2011).

117 **2 Materials and methods**

118 **2.1 Study site**

119 The study was conducted at the Grignon station, an ICOS ecosystem site (ICOS code FR-Gri, class 2 since 2021).  
120 It is a crop field of 19 ha located 40 km west of Paris, in northern France (48.9°N, 1.95°E; elevation 125 m) (**Figure**  
121 **1**). During the study period (2005-2019), the mean annual air temperature and rainfall were 11.2 °C and 586 mm,  
122 respectively. The site has a gentle north-eastward slope of approximately 1%. Agricultural fields mostly surround  
123 the south and west of the study area. The surface soil (0–15 cm layer) is classified as silt loam, with a particle-size  
124 distribution of 98 g kg<sup>-1</sup> sand, 713 g kg<sup>-1</sup> silt, and 189 g kg<sup>-1</sup> clay. The effective soil depth (A + B horizons) varies  
125 from approximately 0.4 m in the north-east to over 1 m in the south-west. Soils across the parcel exhibit calcic  
126 horizons, with average CaCO<sub>3</sub> contents of 3% in the 0–50 cm layer and 20% in the 50–100 cm layer, and an  
127 alkaline soil pH of 7.6. (**Table S1**). The OC content in the surface layers was around 20 g C kg<sup>-1</sup> as reported in  
128 2011 (Loubet et al., 2011).  
129

130  
131 **Figure 1. (A) Map of the ICOS station network across Europe, showing atmosphere (red), ecosystem (green), and ocean**  
132 **(blue) stations. The Grignon site (FR-Gri) is highlighted. (B) The 19-ha field site at FR-Gri, shown in a Google Maps**  
133 **image, with the target area outlined in yellow. The eddy covariance system (white triangle) is located centrally, sur-**  
134 **rounded by its dominant flux footprint (shaded gradient area). The site, with a mixed farm with cattle and sheep housed**  
135 **in the southern buildings, has been cultivated for over 100 years, although the exact start year is unknown. The site is**  
136 **highly fertilised with sewage sludge in the 1980s.**

137  
138 In 2004, as part of implementing reduced tillage in the crop rotation system, the soil was scarified to a depth of 50  
139 cm to reduce compaction. Since then, most tillage operations have been restricted to the superficial layer (0–15  
140 cm), using a stubble cultivator or a clod crusher. Two additional scarification events were carried out: one in 2010  
141 (to a depth of 25 cm) and another in 2012 (to a depth of 40 cm). Additionally, the soil is disturbed to a depth of 5  
142 or 10 cm during seeding operations.  
143

**Table 1. Crop rotation, yield, exports and imports, and nitrogen (N) applied over the 15 years between the two sampling campaigns at the FR-Gri site. Carbon export was evaluated based on the farmer's record of grain, straw, and silage exports. The aerial crop residue return was evaluated based on the exports and the allometric coefficient of the AMG model, as explained in the manuscript. A  $0.44 \text{ g C g}^{-1}$  dry biomass carbon content was assumed to compute the exports and imports. Organic nitrogen was mainly cattle slurry and, on a few occasions, manure. Mineral fertilisation was mainly urea-ammonium-nitrate.**

149 The crops in the rotation system are winter wheat, silage maize (preceded by a mustard catch crop), and winter  
150 barley, with two years of oilseed rape during the period (**Table 1**). These crops are herbaceous, with C3 (wheat,  
151 barley, triticale, oilseed rape, mustard) or C4 (maize) plants. Crop production is primarily exported as grain or  
152 silage (maize), but residues are also exported for use as animal feed and for bioenergy purposes. The average  
153 carbon export was  $470 \pm 54 \text{ g C m}^{-2} \text{ yr}^{-1}$  (**Table 1**). The field received regular applications of slurry and manure,  
154 with an average carbon input of  $114 \pm 13 \text{ g C m}^{-2} \text{ yr}^{-1}$ . The average above-ground biomass crop residues left on  
155 the field were evaluated using the exported biomass and allometric coefficients (Clivot et al., 2019). They represent  
156  $151 \pm 17 \text{ g C m}^{-2} \text{ yr}^{-1}$ , approximately one-third of the exported carbon, which is slightly higher than the amount  
157 imported. The biomass of mustard was not measured but taken equal to the mean estimated biomass of mustard in  
158 France,  $-2 \text{ Mg DM ha}^{-1}$  (Soleilhavoup and Crisan, 2021).

159

## 160 **2.2 Soil sampling schemes**

161 The two campaigns were conducted in different areas around the eddy covariance system. The 2005 campaign  
162 focused on an area representative of the eddy covariance mast's maximum footprint, while the 2019 campaign  
163 encompassed the entire 19 ha field. The footprint determined using the Kljun approach (Kljun et al., 2004, 2015)  
164 was well within the 19-ha field (Figure 1), except on some stable nights when it extended into the surrounding  
165 area. Two different soil sampling strategies were employed during the 2005 and 2019 campaigns (**Figure 2**). In  
166 the 2005 campaign, 100 soil cores were taken using a systematic sampling grid ( $7 \times 7 \text{ m}$ ), and samples were  
167 collected with both 8.3 cm and 8.7 cm inner diameter corers in December 2005, during the winter wheat dormancy  
168 period. Soil cores were divided into seven layers (0-5, 5-10, 10-20, 20-30, 30-40, 40-50, and 50-60 cm). The 2005  
169 campaign results were reported in Schrumpf et al. (2011). In the 2019 campaign, 99 soil samples (20 locations  $\times$   
170 5 depths – 1) were collected in March, following the ICOS protocol (Arrouays et al., 2018; Loustau et al., 2017),  
171 which consists of a stratified simple random sampling design. One sample, located between 60 and 100 cm, was  
172 not reachable due to the high rock density. The field was at that time covered with a mix of catch crops (oats, field  
173 bean, pea, clover, and flax). The studied area was divided into 10 geographically compact equal-area strata (Wal-  
174 voort et al., 2010). Within each stratum, two primary sampling points (SP-I) were randomly selected (simple ran-  
175 dom) for a total of 20 SP-I plots. At each SP-I, five secondary sampling points (SP-II) were randomly selected  
176 within a buffer area of 10 meters, where the soil was sampled using a 5.5 cm inner diameter corer. Each core was  
177 separated into subsamples at depths of 0-5 cm, 5-15 cm, 15-30 cm, 30-60 cm, and 60-100 cm. Finally, cores were  
178 mixed to form a composite sample at each primary location and each layer. The spatial stratification and sampling  
179 point distribution were performed using the R package “*spcosa*” (Walvoort et al., 2010). To ensure comparability  
180 between the 2005 and 2019 sampling campaigns, all SOC stock change analyses presented in this study were  
181 restricted to a spatially comparable subset of the field, which exhibited similar pedological properties in 2005 and  
182 2019 (**Figure S4**). A detailed spatial comparison between the two sampling campaigns, including clustering anal-  
183 yses and sensitivity tests across different spatial subsets, is provided in the Supplementary Material (Figure S1-  
184 S5).

185

186

187 **Figure 2. A) Map of the study area showing the spatial distribution of sampling zones and soil core depth segmentation.**  
 188 **Soil sampling was conducted at two times: in 2005 (black circles) and 2019 (blue diamonds). For the 2019 sampling, the**  
 189 **field was stratified into 10 strata (coloured polygons, labelled 1–10), and the sampling points were randomly located**  
 190 **within each stratum. The 2005 sampling followed a grid-based sampling design that partially covered strata 2, 4, 5, and**  
 191 **8, with the majority of the sampling concentrated in strata 8 and 4. Blue polygon represents the “Reduced field” and**  
 192 **black polygon the “Intersection field”. B) Segmentation of soil cores into depth intervals for two different sampling**  
 193 **protocols: 60 cm cores (six layers: 0–5, 5–10, 10–20, 20–30, 30–40, and 50–60 cm) and 100 cm cores (five layers: 0–5, 5–**  
 194 **15, 15–30, 30–60, and 60–100 cm). Latitude and longitude are shown in WGS 84 coordinates.**

195

### 196 2.3 Soil samples preparation and analyses

197 In the 2005 campaign, all soil samples were preserved at 4°C before processing. The coarse fraction – rock (RF)  
 198 ( $\varnothing > 4$  mm) and root fractions ( $\varnothing > 1$  mm) - were separated from the samples and subsequently air-dried at 40°C.  
 199 The remaining samples were sieved to  $< 2$  mm to obtain the fine earth (FE) fraction and the coarse fraction ( $> 2$   
 200 mm). Subsequently, each fraction was weighted (Schumpf et al., 2011). In the 2019 campaign, samples from SP-  
 201 II plots were air-dried at 30°C and then sieved to separate the FE fraction ( $< 2$  mm). The root and rock fractions  
 202 were oven-dried at 70°C and 105°C, respectively, before weighing. Subsequently, the FE fraction from each depth  
 203 interval of the five SP-II plots was proportionally mixed (based on the weight contribution of each layer) to create  
 204 a composite sample (SP-I). The BD, residual water and FE fraction were computed from the SP-II samples, then  
 205 averaged at the SP-I level, and the C content was measured on the SP-I composite samples. See Arrouays et al.  
 206 (2018) and ICOS protocol (Loustau et al. 2017) for more information. In both campaigns, the FE fraction was then  
 207 split into three subsamples to measure the C content (air-dried sample), residual water (after drying at 105°C) and  
 208 soil bulk density (BD). Soil organic carbon (SOC) content ( $C, g\ kg^{-1}$ ) was determined in the air-dried FE fraction  
 209 by dry combustion (ISO 10694), which measures the total carbon content in the soil. Overall, the soil preparation  
 210 and analysis methods used in 2005 and 2019 were very similar. Carbonate ( $CaCO_3, g\ kg^{-1}$ ) was measured by de-  
 211 termining the loss of carbon dioxide ( $CO_2$ ) after acidification with hydrochloric acid in 2019. The inorganic carbon  
 212 content was also determined in 2019: when  $CaCO_3$  content was lower than  $700\ g\ kg^{-1}$ , the soil inorganic carbon  
 213 (SIC) content was calculated as  $C = 0.12 \times CaCO_3$ . When the  $CaCO_3$  content exceeded  $700\ g\ kg^{-1}$ , to avoid a  
 214 deterioration in the accuracy of organic carbon deduced from total carbon, samples were first treated with HCl to  
 215 eliminate carbonates, and then total carbon was determined as previously explained. The SOC content was then  
 216 computed as the total carbon content minus the inorganic carbon content.

## 217 2.4 Soil data pre-processing

218 Before statistical analysis, missing values in the 2005 dataset were imputed using Ordinary Kriging interpolation  
219 (Goovaerts, 1997), which leverages spatial autocorrelation to provide unbiased and minimum variance estimates  
220 of missing data points. Using spatial coordinates, the target variables were estimated based on interpolated values  
221 derived from a fitted variogram model (Nugget + Spherical) and up to 35 neighbouring data points within a 100-  
222 unit radius. For the 2019 dataset, which had only a single missing value, we used the average value of the corre-  
223 sponding soil layer.

## 224 2.5 Soil carbon stocks calculation using the fixed-depth (FD) approach

225 The soil carbon stock  $SOC_{stock}$  (kg C m<sup>-2</sup>) across the soil layers was calculated following Poeplau et al. (2017):  
226

$$227 \quad SOC_{stock} = \sum_{i=1}^n \frac{m_{FE_i}}{m_{soil_i}} \times BD_i \times \Delta z_i \times SOC_i \times \frac{1}{1000} \times 10000 \quad (1)$$

228  
229 Where  $n$  is the number of layers in which the soil core was divided down to 60 cm,  $i$  is the layer index,  $m_{FE_i}$  (g)  
230 is the mass of fine earth in the layer, and  $m_{soil_i}$  (g) is the total soil mass of the layer (including rocks and roots),  
231  $BD_i$  (g cm<sup>-3</sup>) is the bulk density of the layer,  $\Delta z_i$  is the layer thickness (cm), and  $SOC_i$  (g C kg<sup>-1</sup>) is the SOC content  
232 in the FE fraction in the layer. The factor of  $\frac{1}{1000}$  converts SOC content from g kg<sup>-1</sup> to kg kg<sup>-1</sup>, and the factor of  
233 10000 converts cm<sup>2</sup> to m<sup>2</sup>. The bulk density in each soil layer is defined as the ratio of  $m_{soil_i}$  to the soil core  
234 volume  $V_{sample_i}$ :

$$235 \quad BD_i = \frac{m_{soil_i}}{V_{sample_i}} = \frac{m_{soil_i}}{S_i \times \Delta z_i} \quad (2)$$

237  
238 where  $S_i$  is the sampled surface. Equations (1) and (2) correspond to equations (1) and (2) in Schrumpf et al. (2011)  
239 and were used to compute the stocks for the 2005 samples. We note that when combining equations (1) and (2),  
240 the mass of soil  $m_{soil_i}$  and the layer thickness  $\Delta z_i$  disappear. In the ICOS stock calculation protocol, the bulk  
241 density is therefore no longer used. The SOC stocks are computed based on the surface sampled  $S_i$  and the mass  
242 of fine earth  $m_{FE_i}$  only. By further simplifying the conversion factors, one gets:

$$243 \quad SOC_{stock} = \sum_{i=1}^n \frac{m_{FE_i}}{S_i} \times SOC_i \times 10 \quad (3)$$

245  
246 In equation (3), a term can be identified as the fine earth in each layer,  $FE_i = m_{FE_i}/S_i \times 10$  (kg m<sup>-2</sup>), which gives  
247 the fine earth over the 0-60 cm profile:

$$248 \quad FE_{60cm} = \sum_{i=1}^n \frac{m_{FE_i}}{S_i} \times 10 = \sum_{i=1}^n FE_i \quad (4)$$

250  
251 We note here that these equations are adapted for core sampling. When sampling soils with pits, some corrections  
252 need to be introduced in equations (1-3) to account for large stones and large roots in the pit. The inorganic carbon

253 stock  $SIC_{stock}$  is computed in a similar way as the  $SOC_{stock}$  but replacing the OC content in the FE fraction  $SOC_i$   
 254 by the inorganic carbon content  $SIC_i$ . Finally, the cumulative  $SOC_{stock}^{0-60\text{ cm}}$  was computed after summing the stocks  
 255 per layer.

## 256 2.6 Harmonisation of soil layers in both sampling campaigns

257 To ensure comparability between campaigns, the soil sampling depth (**Figure 2**) of each campaign was harmonised  
 258 into three coarser layers: 0–5 cm, 5–30 cm, and 30–60 cm. Bulk density, rock fragments, and carbon content were  
 259 aggregated using a thickness-weighted mean to account for variable layer depths, while SOC stocks and fine earth  
 260 mass were calculated as cumulative sums across the respective layers. All subsequent SOC stock calculations and  
 261 statistical analyses were performed on these layers. Additional layers are provided in the supplementary material.

## 262 2.7 Soil carbon stocks calculation using the equivalent soil mass (ESM) and SOC stocks changes

263 To properly estimate SOC stocks evolution, one needs to consider changes in SOC content of the soil ( $SOC$ ) but  
 264 also the potential changes in  $BD_i$  due to compaction or decompaction, which may change the fine earth mass  $FE_i$   
 265 in each sampling depth (Lipiec and Hatano, 2003). Additionally, soil erosion driven by rainfall or wind can export  
 266 soil particles – mainly silt and clay - out of the field. Erosion is thought to be negligible at the FR-Gri site due to  
 267 a slight slope and systematic winter inter-cropping. Decompaction may have happened since the site was converted  
 268 to reduced tillage from 2000 onwards (Loubet et al., 2011), but compaction in subsoil may also occur due to  
 269 repeated surface traffic by heavy machinery (Liebhard et al., 2025; Lu et al., 2021). To consider possible changes  
 270 in  $BD_i$ , the SOC stock evolution was estimated using the equivalent soil mass method (ESM), where the SOC  
 271 stock is integrated down to a varying depth corresponding to a reference soil mass that is set equal for each cam-  
 272 paign (Ellert and Bettany, 1995; von Haden et al., 2020; Lee et al., 2009; Wendt and Hauser, 2013). This approach  
 273 has the advantage of accounting for a common sampling bias associated with the hydraulic corer, namely soil  
 274 compaction.

275 The ESM-based SOC stock was computed using the R function “*SimpleESM*” (Ferchaud et al., 2023), which im-  
 276 plements the classical ESM method (Ellert and Bettany, 1995) and ESM2, a model-based approach incorporating  
 277 cubic splines (Wendt and Hauser, 2013). The reference fine earth mass ( $FE_{ref}$ ) was derived from the median  
 278 values in the 2005 dataset for the aggregated soil layers: 0–5 cm, 5–30 cm, and 30–60 cm (**Table 1**). The total FE  
 279 in the 0–60 cm layer ranged from 852 to 967 kg m<sup>-2</sup> in 2005, and from 831 to 953 kg m<sup>-2</sup> in 2019 (**Table S4**).  
 280

281 **Table 2. Reference fine earth mass ( $FE_{ref}$ ) per layer used in the equivalent soil mass approach (ESM).**

Layer	Upper depth	Lower depth	$FE_{ref}$ kg m <sup>-2</sup>
	cm		
L1	0	5	63.2
L2	5	30	372.6
L3	30	60	453.1

282  
 283 In the “classical” ESM approach (Ellert and Bettany, 1995), SOC stock is calculated by 1 mm increments (Autret  
 284 et al., 2016; Mary et al., 2020). In brief, soil depth is discretised into elementary layers of 1 mm thickness, with  
 285 FE density (g cm<sup>-3</sup>) and carbon content (g kg<sup>-1</sup>) assigned to each 1 mm layer. Since both FE density and the SOC  
 286 content are typically reported as average values over macro-layers (e.g., 0–5 cm), these values are assumed to be  
 287 constant within each 1 mm sublayer. Subsequently,  $FE_i$  and  $SOC_{stock_i}$  are then computed cumulatively until the

288  $FE_{ref}$  is reached. This approach is referred to as “*ESM non model*” by Peng et al. (2024). The ESM2 approach is  
 289 based on the "material coordinate system" (Lee et al., 2009; McBratney and Minasny, 2010) or the "cumulative  
 290 coordinates approach" (Rovira et al., 2015). This method uses a *post-hoc* model - a cubic spline interpolation - to  
 291 mathematically adjust SOC measurements to a common fine earth mass (von Haden et al., 2020; Wendt and  
 292 Hauser, 2013). As both ESM and ESM2 methods yielded similar results (**Figure S6**), only ESM outcomes are  
 293 reported in the following.

## 294 **2.8 Statistical inference for assessment of the carbon stock change**

295 Unequal variance t-tests (Welch’s t-test) were applied to assess significant differences between the two campaigns’  
 296 means of SOC stocks estimated by FD and ESM approaches and other soil variables. The Welch’s t-test value was  
 297 calculated as:

$$298 \quad t = \frac{(\widehat{X}_{2005} - \widehat{X}_{2019})}{\sqrt{\widehat{V}(\widehat{X}_{2005}) + \widehat{V}(\widehat{X}_{2019})}} \quad (5)$$

299 Where  $\widehat{X}$  is the estimated mean of the soil property X,  $\widehat{V}(\widehat{X})$  is the estimated sampling variance of the estimated  
 300 mean, and indexes stand for the campaign years. A design-based approach was used to estimate the means and  
 301 sampling variances (de Gruijter et al., 2006). The sampling variances of the two campaigns were estimated sepa-  
 302 rately and considered unequal. For the 2019 campaign, a stratified random sampling method with equal-area strata  
 303 was employed. With the same number of sites per stratum, the mean and the sampling variance are estimated as:

$$304 \quad \widehat{X} = \frac{1}{N} \sum_{i=1}^N X_i \quad (6)$$

$$305 \quad \widehat{V}(\widehat{X}) = \sum_{h=1}^H w_h^2 \widehat{V}(\widehat{X}_h) = \frac{1}{4} \sum_{h=1}^H \widehat{V}(\widehat{X}_h) \quad (7)$$

306 Where  $X_i$  is the measured soil property at location  $i$ ,  $N$  is the total number of samples over all strata,  $\widehat{V}(\widehat{X}_h)$  is the  
 307 sampling variance of stratum  $h$ ,  $w_h^2 = \frac{1}{4}$  is the weight of stratum  $h$ , and  $H$  is the number of strata.

308 For systematic random sampling (2005 campaign), the mean estimate is simple (Eq. 6), but there is no unbiased  
 309 estimate of the sampling variance. We implemented the approximation suggested by Brus and Saby (2016), where  
 310 the systematic random sample is treated as a stratified simple random sample. The sampling units were thus clus-  
 311 tered by 2 based on their spatial coordinates into  $H = n/2$  clusters ( $n = 100$ ) using a  $k$ -means algorithm. The 2  
 312 sampling units of a cluster were treated as a simple random sample from a stratum, and the variance was estimated  
 313 with eq. (7) with  $H = 50$ . The weights were computed by  $w_h^2 = n_h/n$ , where  $n_h = 2$  is the number of units per  
 314 cluster. The 95% confidence interval is given by:

$$315 \quad \widehat{X} \pm t_{2.5}^{N-H} \sqrt{\widehat{V}(\widehat{X}_h)} \quad (8)$$

316 Where  $t_{2.5}^{N-H}$  is the 2.5 quantile of a  $t$  distribution where  $(N - H)$  approximates the degrees of freedom. For the  
 317 2005 campaign, the degree of freedom was  $N - H = 100 - 50 = 50$ . In 2019, when the *Complete field* was con-  
 318 sidered, there were  $H = 10$  strata of 2 units each, leading to a total number of sampling points  $N = 20$  (called SP-I  
 319 in ICOS), leading to  $N - H = 10$ . When part of the field was considered, both the number of samples and  $H$   
 320 diminished leading to  $N - H < 10$ . In 2005 and 2019, equations (7-9) were used to compute the carbon stock  
 321 statistics for each sampling depth available and over aggregated layers 0-15 cm, 15-30 cm and 30-60 cm. We also  
 322 computed the minimum detectable difference (MDD) based on a t-test with 95% confidence and 90% power ( $\alpha =$   
 323  $0.05$ ,  $\beta = 0.10$ ).

324 Finally, we performed an additional statistical analysis to quantify the magnitude of SOC stock changes between  
 325 2005 and 2019 by calculating effect sizes using Hedges'  $g$ . This metric is a standardised mean difference method  
 326 that includes a correction for small sample sizes (Hedges, 1981), which was especially the case when using the  
 327 Reduced and Intersection fields, leading to 14 and 8 samples, respectively. Confidence intervals for effect-size  
 328 estimates were computed using 20000 nonparametric bootstraps with resampling and the bias-corrected and ac-  
 329 celerated (BCa) method (Canty et al., 2024; Efron, 1987; Kirby and Gerlanc, 2013). Negative values of Hedges'  
 330  $g$  indicate a reduction in SOC stocks from 2005 to 2019, while positive values indicate an increase. If the confi-  
 331 dence intervals (CIs) include zero, it suggests that there is no significant difference in SOC stocks between the two  
 332 sampling years. These analyses were performed using the R package "*bootES*" (Kirby and Gerlanc, 2013).  
 333 See the equations (s1-s5) in the supplementary material.

## 334 2.9 Simulation of carbon stock evolution with the AMG model

335 We computed the SOC stock changes using the agricultural soil carbon model AMG (Clivot et al., 2019) to com-  
 336 pare with measured changes in SOC stock in the surface soil layer (0-30 cm). AMG is a relatively simple soil  
 337 carbon model that simulates SOC stocks by partitioning the soil carbon into three pools: (1) a pool receiving  
 338 organic C inputs from crop residues, roots, and exogenous organic matter (EOM), (2) an active organic C pool  
 339 subject to decomposition, and (3) a stable organic C pool. As stable C presents slow turnover, considering the  
 340 timescale of the simulation, this pool is considered inert in the model and neither decomposes nor receives new C  
 341 inputs.

342 A proportion ( $h_a$ ) of all the C inputs to the soil is allocated to the active C pool, while the remaining proportion  
 343 ( $1 - h_a$ ) is considered mineralised. The active C pool decomposes following first-order kinetics, with a rate con-  
 344 stant ( $k$ ) that depends on climate variables (annual temperature, precipitation, and potential evapotranspiration)  
 345 and soil properties (clay content, carbonate content, pH, and C:N ratio). The C inputs to the soil include above-  
 346 ground crop residues and organic amendments from manure and slurry as listed in **Table 1**, plus the belowground  
 347 crop residues and rhizodeposition estimated from allometric equations based on the aboveground biomass (Clivot  
 348 et al., 2019, 2023). Roots and rhizodeposition C inputs down to a considered depth  $i$  are computed as:

$$349 C_{below\ ground\ inputs}(i) = \frac{DM_{AG}}{SRR} * 0.4 * 1.65 * (1 - \beta^i) \quad (9)$$

350 Where  $DM_{AG}$  is the above-ground biomass,  $SRR$  is the shoot-to-root-ratio, 0.4 is the carbon content of the roots  
 351 (40%), 1.65 is a factor accounting for the dead roots and rhizodeposition, assumed to be 65% of the living roots  
 352 C, and  $(1 - \beta^i)$  accounts for the roots' distribution in the soil, where  $\beta$  is a crop-dependent parameter.

353 The SOC stock changes were simulated on an annual timestep over the period 2005–2040, considering the 0-30  
 354 cm depth layer, which generally corresponds to the managed soil layer in cropland systems, where most crop roots  
 355 and residue inputs occur. The baseline SOC stock in the 0-30 cm layer was set to 8.25 kg C m<sup>-2</sup>, based on meas-  
 356 urements from 2005. The proportion of the stable organic carbon pool was set to 65% ( $C_s = 0.65$ ), as proposed by  
 357 Clivot et al. (2019) for agricultural fields with a long-term history of cultivation. To assess model sensitivity, we  
 358 performed additional simulations by varying key management and environmental factors and comparing to a base  
 359 scenario: (1) residue returns to the soil were increased to 100% of the available residues, (2) organic amendments  
 360 were either eliminated (set to zero) or doubled (multiplied by two), (3) meteorological conditions were set to the

361 pre-2005 period by repeating the 1987–2004 weather data for the 2005–2040 period, and (4) the proportion of  
362 stable organic carbon pool (Cs) was set to 0.63 and 0.75 as independent estimates on a nearby soil reported by  
363 Kanari et al (2022) to illustrate the model’s response to this critical soil carbon parameter. In the base scenario, (1)  
364 the residue returns and (2) the organic amendments were set according to Table 1, (3) the meteorological conditions  
365 were those measured at the site between 2005 and 2019, and then repeated to 2040, and (4) Cs was set to 0.65.

## 366 **2.10 Carbon flux balance derived from Eddy Covariance measurements**

367 The carbon flux balance was estimated from 2006 to 2010 in Loubet et al. (2011), based on the Eddy Covariance  
368 (EC) micrometeorological method. The net biome productivity (NBP), representing the carbon balance of the field,  
369 was computed as:

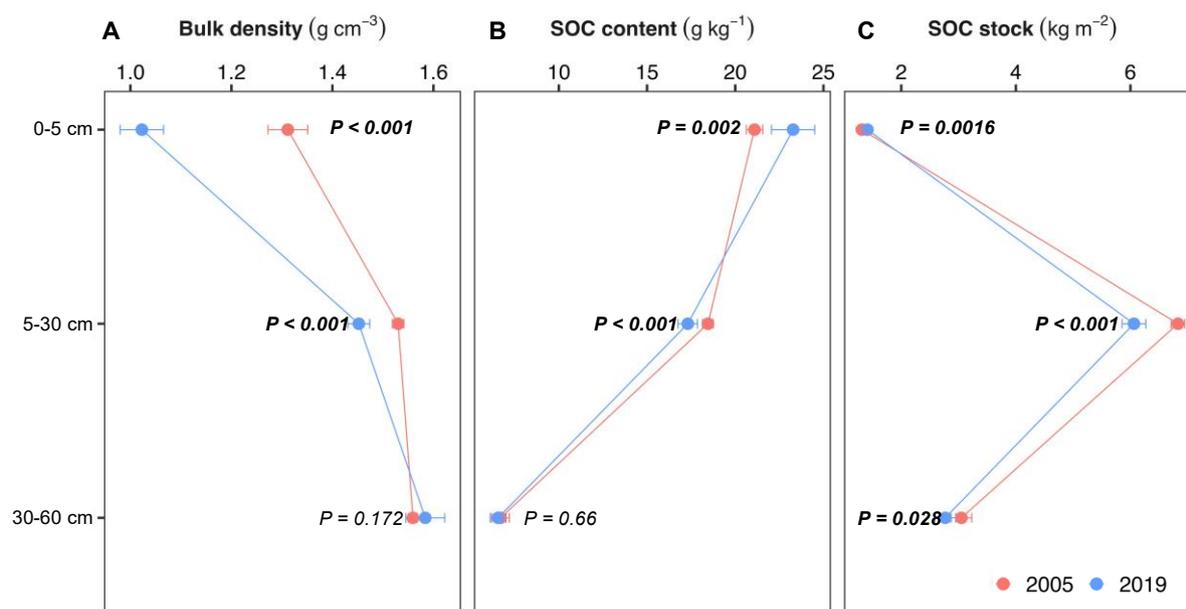

$$370 \quad NBP = NEE + F_{orga.fert} + F_{seeds} - F_{leach} - F_{harvest} \quad (10)$$

371 where  $NEE$  is the net ecosystem exchange of  $CO_2$  flux over time,  $F_{orga.fert}$  is the carbon input through organic  
372 fertilisation,  $F_{seeds}$  is the carbon input through seedling,  $F_{leach}$  is the organic and inorganic carbon losses by lix-  
373 iviation, and  $F_{harvest}$  is the carbon export through harvest. See Loubet et al. (2011) for details. We limited the  
374 carbon balance study to the 2006–2010 period published in Loubet et al. (2011). Indeed, computing the full period  
375 2005–2019 carbon balance requires filling a year gap in 2018 and processing the leaching flux, which implies crop  
376 and leaching modelling, as well as an uncertainty analysis that goes beyond the scope of this manuscript.

## 377 **3 Results**

### 378 **3.1 Summary statistics of soil properties**

379 Statistical analysis confirmed a significant decompaction from 2005 to 2019, evidenced by a reduction in bulk  
380 density, particularly in the 0-5 cm ( $p < 0.001$ ) and 5-30 cm ( $p < 0.001$ ) layers (**Figure 3, Table S5**). BD decreased  
381 by ~25% in the 0-5 cm layer and by ~5% in the 5-30 cm layer, while the 30–60 cm layer presented a slight but  
382 non-significant increase. Similar results were observed for the fine earth density (Table S4). For the entire 0-60  
383 cm profile, the average soil stock ( $FE_{0-60cm}$ ) in 2005 was  $882.5 \text{ kg m}^{-2}$ , which was approximately 5% greater than  
384 in 2019 ( $840.1 \text{ kg m}^{-2}$ ). Meanwhile, the soil mass in the 0-5 cm layer decreased by about 25%. The SOC contents  
385 varied from 2005 to 2019 (**Figure 3, Table S5**). In the 0–5 cm layer, SOC contents were significantly higher in  
386 2019 than in 2005 by around  $2.2 \pm 0.57 \text{ g C kg}^{-1}$  ( $p = 0.002$ ). In contrast, SOC content in the 5-30 cm layer was  
387 significantly lower by 6.2% in 2019 compared to 2005, with a mean difference of  $-1.14 \pm 0.28 \text{ g C kg}^{-1}$  ( $p < 0.001$ ).  
388 In the 30–60 cm layer, SOC contents remained statistically unchanged  $-0.14 \pm 0.31 \text{ g C kg}^{-1}$ ,  $p = 0.66$ ).

390

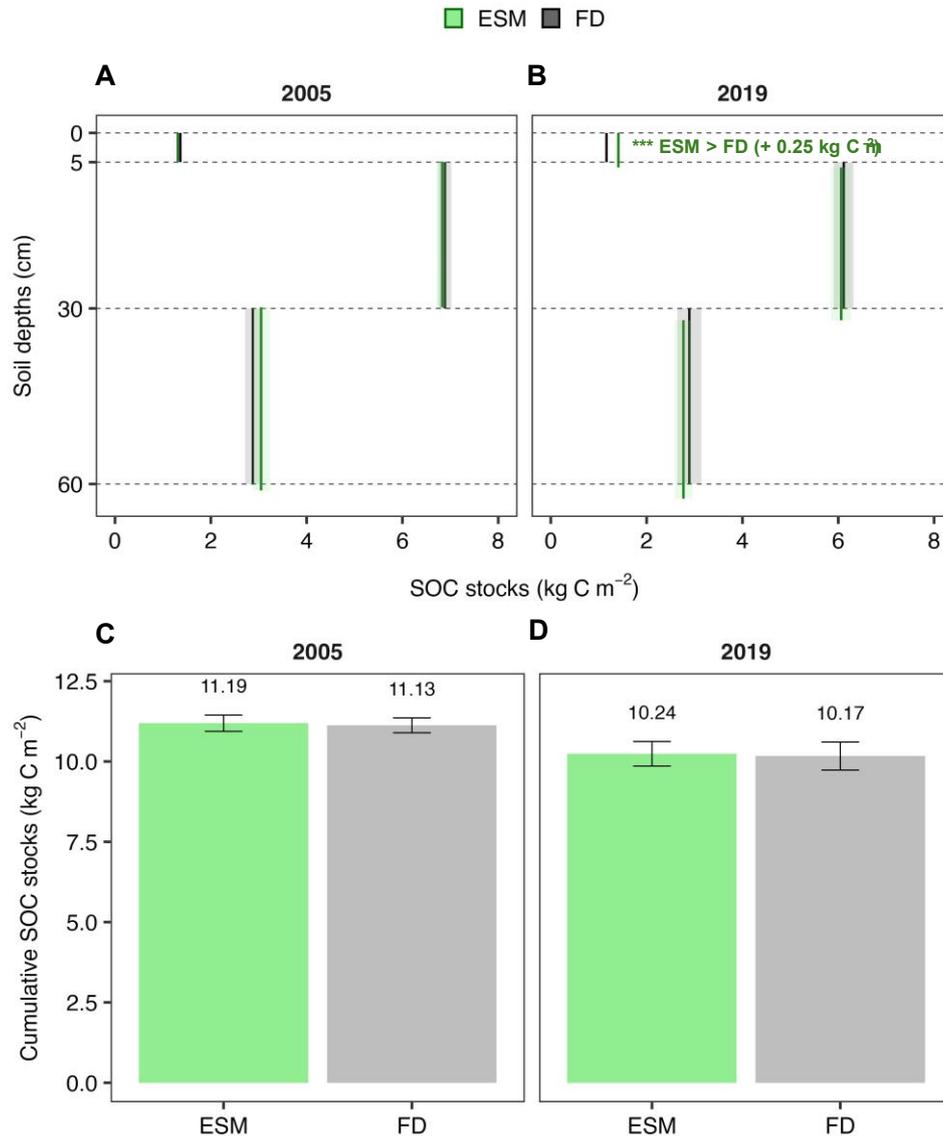

391 **Figure 3.** Mean of bulk density, soil organic carbon (SOC) contents, and ESM-based SOC stocks with their correspond-  
 392 **ing confidence intervals (CIs) in the 2005 and 2019 campaigns across three soil layers (0-5, 5-30, 30-60 cm). Mind that**  
 393 **the layer depths given here do not correspond to absolute depths since the ESM method implies varying depths with**  
 394 **time. The real depths corresponding to these layers are shown in Figure 5B.**

395

### 396 3.2 Differences between FD and ESM-based SOC stocks

397 The FD and ESM approaches were statistically similar in 2005 across the three soil layers (Figure 4A) and only  
 398 showed significant differences in the 0-5 cm soil layer in 2019 (**Figure 4B**). Both approaches did not differ when  
 399 comparing the cumulative SOC stocks up to ~60 cm (all  $p > 0.5$ , **Figure 4C-D**).

400

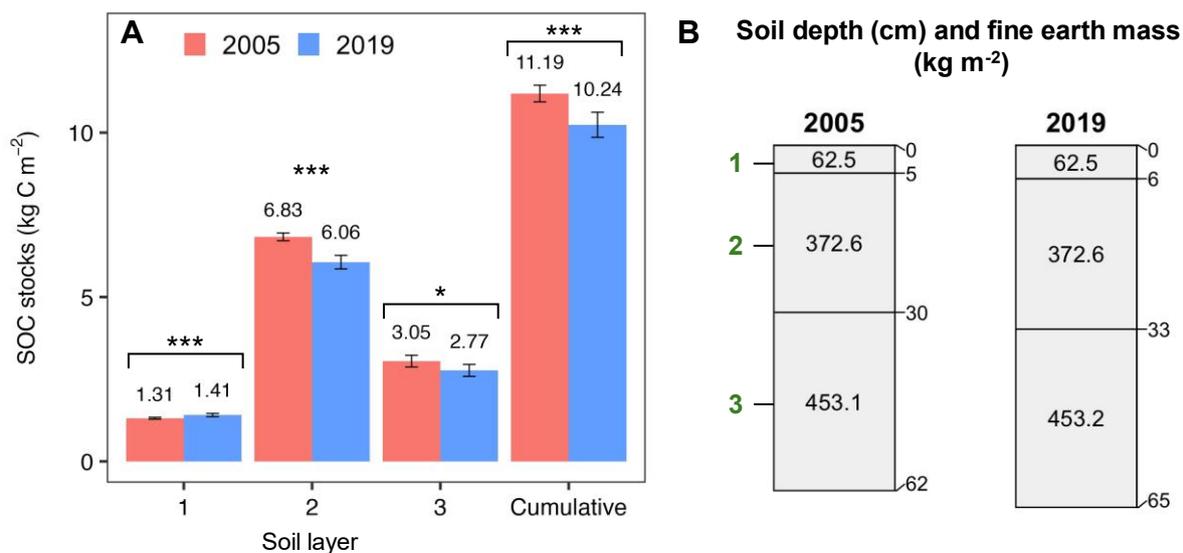

401  
 402 **Figure 4.** Soil Organic Carbon stocks and corresponding confidence intervals (error bars and shaded ribbons) estimated  
 403 using Fixed Depth (FD) and Equivalent Soil Mass (ESM) approaches. Panels A and B show SOC stocks per depth range  
 404 for 2005 and 2019. Solid lines (vertical) represent mean SOC stocks across the entire depth range. Dashed horizontal  
 405 grey lines represent the fixed soil depth layers, aggregated into 0–5 cm, 5–30 cm, and 30–60 cm. If the thickness of the  
 406 ESM-adjusted depth falls outside the upper or lower bounds of the fixed soil depth, it indicates that a depth adjustment  
 407 was made during the ESM computation. Panels C and D show cumulative SOC stocks over the 0–60 cm layer for 2005  
 408 and 2019. Asterisks denote significant differences between SOC stock estimation methods ( $P < 0.001$  corresponds  
 409 to \*\*\*).

410

### 411 3.3 Soil carbon stock changes over time

412 The mass-equivalent depth (**Figure 5B**) varied between years according to the reference soil mass shown in **Table**  
 413 **2**. On average, the mass-equivalent depths in 2019 were 0–6 cm, 6–33 cm, and 33–65 cm. In 2005, the soil depth  
 414 adjustment was minimal compared to the sampling depth, with an increase of  $2 \pm 0.7$  cm in the third layer (30–62  
 415 cm). The ESM estimates indicated a cumulative loss of soil organic carbon over the three layers of  $-0.95 \pm 0.20$  kg

416 C m<sup>-2</sup> between 2005 and 2019 (**Figure 5A**). In the 0-5 cm layer, a higher SOC stock was measured in 2019 com-  
 417 pared to 2005 (+0.10 ± 0.02 kg C m<sup>-2</sup>). The second layer (sampling depth of 5–30 cm) showed a lower SOC stock  
 418 in 2019, with a SOC stock change of about 0.8 ± 0.10 kg C m<sup>-2</sup>. In the deeper layer (sampling depth of 30–60 cm),  
 419 SOC stock changes showed a less significant reduction of about 0.28 ± 0.11 kg C m<sup>-2</sup>. Effect-size comparisons  
 420 between the two campaigns across the three layers confirmed the significance of the SOC changes between 2005  
 421 and 2019 (**Figure S8**). A finer vertical analysis (Figure S9) indicates that the SOC stocks in 2019 were higher in  
 422 the layer L1 (~0-5 cm), then decreased between layers L3 and L5 (~20 and ~40 cm), before increasing again in  
 423 layers L6 and L7 (~ 40 - 60 cm).  
 424

425  
 426 **Figure 5. Mean soil organic carbon (SOC) stocks (kg C m<sup>-2</sup>) estimated using the Equivalent Soil Mass (ESM), along**  
 427 **with their corresponding confidence intervals (error bars), for the 2005 and 2019 campaigns (Panel A). Adjusted soil**  
 428 **depth (cm) and fine earth mass (kg m<sup>-2</sup>) are also shown in Panel B. Asterisks denote significant differences between**  
 429 **campaigns:  $P < 0.001$  (\*\*\*),  $P < 0.01$  (\*\*),  $P < 0.05$  (\*).**

430

### 431 3.4 Cumulative SOC stocks

432 Across the 13.25-year monitoring period, the cumulative SOC stocks up to the sampling fixed depth of 0-60 cm  
 433 exhibited a statistically significant decline ( $p < 0.05$ ) of approximately  $0.95 \pm 0.22$  kg C m<sup>-2</sup> ( $p < 0.001$ ; MDD <  
 434 observed differences, **Table 3**). A similar decline was found using the ESM and the FD. Overall, both SOC esti-  
 435 mation approaches indicate an average SOC loss of approximately  $72 \pm 16$  g C m<sup>-2</sup> yr<sup>-1</sup> over the 13.25-year period.  
 436 In terms of proportional reduction relative to the 2005 baseline, ESM-based SOC stocks decreased by -8.2% in  
 437 the ~0–30 cm layer and -8.5% in the ~0–60 cm layer. These losses translate to annualised losses of approximately  
 438 -0.62% to -0.89% yr<sup>-1</sup>, when referenced to the 2005 SOC stocks baseline.

439 **Table 3. Summary of soil organic carbon (SOC) stock changes between 2005 and 2019 in the “Reduced field” at the FR-**  
 440 **Gri site, assessed for the 0–30 cm and 0–60 cm soil layers using both the Equivalent Soil Mass (ESM) and Fixed-Depth**  
 441 **(FD) approaches. SOC changes are reported in absolute terms (kg C m<sup>-2</sup>) followed by their standard error, relative**  
 442 **change (% of initial stock), and as annualised rates. The Minimum Detectable Difference (MDD) represents the smallest**  
 443 **true difference that can be statistically detected given the observed variability and sample size. If the observed SOC**  
 444 **stock change exceeds the MDD and  $p < 0.05$ , the change is considered detectable. If the SOC stock change is less than**  
 445 **the MDD, the change is not statistically distinguishable. A large MDD reflects high variability or limited sensitivity,**  
 446 **whereas a small MDD indicates high precision in detecting changes in SOC stock. These estimates were also used as**  
 447 **input parameters for the AMG model simulations.**

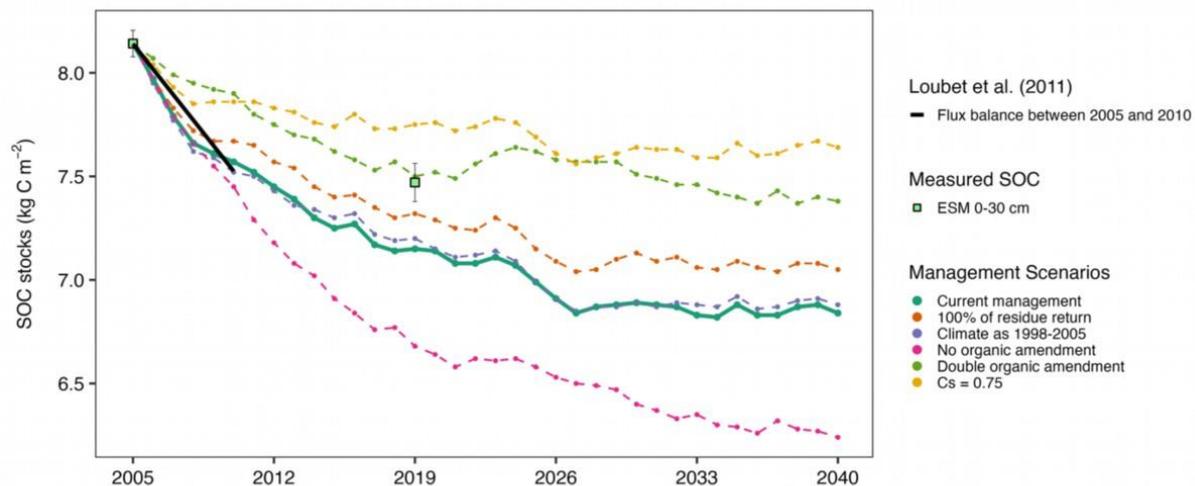

Metric	Equivalent Soil Mass		Fixed depth	
	~ 0-30 cm * 435.1 kg m <sup>-2</sup>	~ 0-60 cm 887.6 kg m <sup>-2</sup>	0-30 cm *	0-60 cm
2005 SOC stocks (kg C m <sup>-2</sup> )	8.14 ± 0.06	11.19 ± 0.13	8.25 ± 0.08	11.12 ± 0.12
2019 SOC stocks (kg C m <sup>-2</sup> )	7.47 ± 0.09	10.24 ± 0.16	7.28 ± 0.09	10.17 ± 0.18
SOC stock change (kg C m <sup>-2</sup> )	-0.67	-0.95	-0.97	-0.96
Standard Error difference (kg C m <sup>-2</sup> )	0.11	0.04	0.12	0.04
Lower CI difference (kg C m <sup>-2</sup> )	-0.90	-1.37	-1.22	-1.40
Upper CI difference (kg C m <sup>-2</sup> )	-0.44	-0.53	-0.72	-0.51

450

### 451 3.5 Comparison of measured SOC stock changes with estimations obtained with the AMG model

452 The AMG model was used to simulate the evolution of soil organic carbon stock from 2005 to 2040 in the 0-30  
 453 cm layer, based on the cropping system, imports and exports, and computing the return of plant residues using  
 454 allometric relationships. Under the baseline scenario, the model exhibited a declining trend in SOC stocks (Figure  
 455 6), which aligns with the decrease observed using the ESM approach in the 0-30 cm layer. The AMG model  
 456 simulated a decrease in SOC stock from 8.24 kg C m<sup>-2</sup> in 2005 to 7.25 kg C m<sup>-2</sup> in 2019, reflecting a cumulative  
 457 loss of approximately -0.99 kg C m<sup>-2</sup> (-12%) over 13.25 years. This modelled SOC loss is larger than the mean  
 458 SOC stock change estimated using the ESM approach in the 0-30 cm layer (-0.67 kg C m<sup>-2</sup>), and slightly outside  
 459 the associated confidence intervals (95% CI: -0.90 to -0.44 kg C m<sup>-2</sup>; Table 3). SOC stocks appear to approach a  
 460 quasi-steady-state from 2027 onwards, with fluctuations of ±0.02 to ±0.04 kg C m<sup>-2</sup> yr<sup>-1</sup>. By 2040, SOC stocks are  
 461 projected to decrease to 6.94 kg C m<sup>-2</sup>, representing an approximate 15% reduction from the 2005 baseline. Both  
 462 the AMG model and measured SOC stocks were consistent with the flux balance approach reported by Loubet et  
 463 al. (2011), during the early period from 2006 to 2010. The overall loss over 22 years (2005-2027) would then be  
 464 of around 1.3 kg C m<sup>-2</sup>, or 13 Mg C ha<sup>-1</sup>, which amounts to 0.059 Mg ha<sup>-1</sup> yr<sup>-1</sup>. Overall, the sensitivity analysis  
 465 across five scenarios reveals a consistent decline in SOC, with cumulative losses ranging from 5 to 18% by 2019  
 466 and from 6 to 23% by 2040. Increasing the residue return leads to a stabilisation of the SOC stock at 7.15 kg C m<sup>-2</sup>,  
 467 instead of 6.95 kg C m<sup>-2</sup>, while doubling the organic carbon amendment would lead to an equilibrium of 7.48  
 468 kg C m<sup>-2</sup>. On the contrary, suppressing the organic carbon amendment would lead to a stabilisation of 6.34 kg C  
 469 m<sup>-2</sup>. The simulation with a climate corresponding to 1998-2005 (slightly colder, with a temperature of -0.3°C  
 470 compared to 2005-2019) had no detectable effect on the simulated soil C stock (Figure 6).

471  
 472  
 473 **Figure 6. Soil organic carbon (SOC) stock in the 0-30 cm depth as simulated by the AMG model (plot lines), measured**  
 474 **by soil sampling in 2005 and 2019 and computed using the equivalent soil mass (ESM; light-green square). The error**  
 475 **bars show the sampling standard error. Flux balance over the 2006-2010 period (black line) as published in Loubet et**  
 476 **al. (2011). Cs denotes the proportion of stable carbon pools in the model.**

477 **4 Discussion**

478 **4.1 Effects of sampling depth and computation methods on the evaluation of organic carbon stock**  
 479 **changes evaluation**

480 Our results show that cumulative SOC stock changes between 2005 and 2019 under reduced tillage management  
 481 were similar between the FD and ESM approaches only when SOC stocks were integrated over the complete 0–  
 482 60 cm profile, differing by just 3% in this layer ( $p > 0.80$ ). In contrast, SOC stock changes differed between  
 483 approaches in the surface soil ( $\leq 30$  cm). Previous studies have documented misleading interpretations of SOC  
 484 stock increases resulting from reduced or no-tillage practices when using the FD approach at shallow depths ( $\leq 30$   
 485 cm) (Du et al., 2017; Xiao et al., 2020). Our results support this in the 0-5 cm layer, where FD indicates SOC stock  
 486 losses while ESM shows gain (**Table S5, Figure S8**). Indeed, FD approaches are prone to bias when soil bulk  
 487 density or SOC content changes, irrespective of the soil management (von Haden et al., 2020). Because BD often  
 488 varies with management in agricultural soils, especially at shallow depths ( $\leq 30$  cm), multilayer sampling and  
 489 equivalent soil mass approaches are essential to capture the temporal response of SOC stock in shallow layers  
 490 (Wendt and Hauser, 2013; Xiao et al., 2020). At the FR-Gri site, the topsoil (0–15 cm) is frequently disturbed by  
 491 shallow tillage using a stubble cultivator or clod crusher, and deep tillage operations have occasionally been ap-  
 492 plied to depths of up to 40 cm. In addition to residue return, these practices influence BD and soil mass distribution,  
 493 particularly within the upper 40 cm of the profile. Additionally, the potential compaction caused by repeated ma-  
 494 chinery traffic cannot be excluded (Hamza and Anderson, 2005), as compaction tends to accumulate over time  
 495 below 40 cm due to the limited tillage operations in the subsoil (Zhang et al., 2024). Roots may also alter BD,  
 496 including in subsurface layers, by modifying the physical properties (e.g., aggregation, porosity) as roots effi-  
 497 ciently explore deeper layers. At the FR-Gri site, we observe a significant decrease in BD in the 0-5 cm and 5-30  
 498 cm layers, with no significant change in the lower layer (30-60 cm) (**Table S4**). Likewise, roots may contribute to  
 499 subsoil SOC stocks through root growth, biomass accumulation, and rhizodeposition. The rhizodeposition process  
 500 may account for up to 65% of root carbon (C) and ~10% of total photosynthesised carbon, as shown for maize

501 (Tardieu, 1988) and wheat (Zhang et al., 2020; Zou et al., 2022), which are the main crops at the FR-Gri site. Fan  
502 et al. (2016) reported that approximately 95% of root biomass lies above 100 cm. In our field, 20% of the SOC  
503 stock changes occurred in the 30-60 cm layer, confirming that sampling to at least 60 cm better captures root-  
504 related C inputs and reduces SOC bias estimate, as also emphasised by Baker et al. (2007) and Wendt and Hauser  
505 (2013). Furthermore, SOC stock estimates in more profound and multiple layers provide valuable insights into  
506 SOC dynamics across the profile, as mineralised carbon may percolate and accumulate in subsoil layers (Rumpel  
507 and Kögel-Knabner, 2011).

#### 508 **4.2 Possible causes of the observed SOC stock changes over 13.25 years**

509 SOC stock losses in cropland systems under various management practices have been widely reported in European  
510 studies (De Rosa et al., 2024). A major cause of carbon losses is the imbalance between carbon imports and ex-  
511 ports, which progressively leads to a shift in the carbon stock from one state to a new one, higher if the imbalance  
512 is an excess of imports or lower in the opposite case (Ingwersen et al., 2024; Poyda et al., 2019). Over the 13.25-  
513 year period (2005–2019), the FR-Gri site has experienced a decrease in SOC stock of  $0.95 \text{ kg C m}^{-2}$  [95% CI: 0.51-  
514 1.4]. Our study has evidenced that C losses in the intermediate soil layers (5-40 cm) are not offset by gains below,  
515 down to a depth of approximately 60 cm (~0-5 and 40-60 cm). Overall, the cropping system history at FR-Gri  
516 resulted in a carbon stock decrease of  $72 \pm 16 \text{ g C m}^{-2} \text{ yr}^{-1}$  over the observed 13.25-year period in the ~0-60 cm  
517 soil layer, irrespective of the SOC estimation method. We hypothesise that SOC decline is primarily related to an  
518 imbalance during that period between carbon imports, limited by reduced crop residue return, and high biomass  
519 exports. The FR-Gri site has been under continuous cropland management for over 100 years, with reduced tillage  
520 and crop rotation introduced in the past two decades. In the 1980s, the field received an unquantified but significant  
521 amount of organic matter inputs from wastewater treatment plants, which may explain the high carbon stocks  
522 observed in 2005. Moreover, since 2004, the increased export of wheat straw for bioenergy has reduced crop  
523 residue returns, while the use of organic amendments has been limited (Table 1). This shift in management prac-  
524 tices may have contributed to a long-term imbalance between C imports and exports, leading to SOC stock de-  
525 clines, as the field exports were, on average, around three times higher than imports and twice higher than the  
526 combined import and aerial residue return. The AMG simulations corroborate this hypothesis, showing a decrease  
527 primarily attributed to the low residue return and limited organic C application. At the same time, the slight shift  
528 in meteorological conditions ( $+0.3 \text{ }^\circ\text{C}$  air temperature) during that period has no significant effect on the simulated  
529 soil C stock (**Figure 6**).

530 Different patterns have been reported in long-term experiments conducted under similar pedoclimatic conditions.  
531 In a well-drained Haplic Luvisol under a temperate climate, Dimassi et al. (2014) demonstrated that changes in  
532 SOC stock under residue removal varied over time, exhibiting alternating phases of accumulation and depletion.  
533 The most substantial depletion occurred around 2002 ( $-0.033 \text{ kg C m}^{-2} \text{ yr}^{-1}$ ), possibly reflecting the lagged effects  
534 of residue removal between 1982 and 1994, as well as the impact of climate change. In contrast, the SOC stock  
535 increased in 2011 after residues were returned after 1994. Furthermore, SOC stocks increased in the upper soil  
536 layer (0-10 cm) but were offset by losses at depth (10-28 cm), resulting in near-neutral changes in SOC stock over  
537 the profile. These trends were later confirmed by Mary et al. (2020), who conducted additional sampling in 2017.  
538 Unlike the long-term experiments of Dimassi et al. (2014) and Mary et al. (2020), where surface gains largely  
539 compensated subsoil losses at the profile scale, SOC losses at FR-Gri were dominated by sustained carbon deficits

540 in intermediate layers, resulting in a net negative balance. However, as we hypothesised here, Dimassi et al. (2014)  
541 suggested that crop management practices, such as residue removal, crop rotation (C3 vs. C4), and catch crops,  
542 mediate C sequestration under similar soil tillage conditions.

543 The relatively high initial SOC stocks at FR-Gri reflect the previously high though unrecorded C inputs (from  
544 wastewater treatment plants) and lower residue exports. This may further contribute to the observed decline in  
545 SOC stock, as C inputs decreased during the 2005-2019 period, despite the presence of substantial organic inputs.  
546 In terms of soil processes, SOC stock declines during this period likely reflect an imbalance between SOC miner-  
547 alization and stabilization processes rates, likely triggered by high fresh plant inputs with low C: N ratio, organic  
548 amendments, nitrogen-rich fertilisation (193 kg N ha<sup>-1</sup>) and environmental conditions favouring microbial activity  
549 and SOC mineralisation (Bernard et al., 2022; Ceschia et al., 2010; Loubet et al., 2011). The depleting effect of  
550 nitrogen-rich inputs was also observed by Dimassi et al. (2014), who found that SOC was depleted under a crop  
551 rotation without a C4 plant and increased after the establishment of a catch crop (oats/vetch).

552 Keel et al. (2019) reported ESM-based SOC stock losses ranging from 0.01 to 0.135 kg C m<sup>-2</sup> yr<sup>-1</sup> across various  
553 crop systems in Switzerland, with an average loss of 0.034 kg C m<sup>-2</sup> yr<sup>-1</sup> in the topsoil (~0–20 cm). Their highest  
554 SOC stock losses were observed under a crop rotation similar to that of FR-Gri, with a comparable initial stock  
555 (~7 kg C m<sup>-2</sup> in the 0–20 cm layer), but implemented on an Orthic Luvisol. We notice that their C inputs from  
556 residue return and organic fertilisation (0.090–0.32 kg C m<sup>-2</sup> yr<sup>-1</sup>) are comparable to ours (0.265 ± 0.030 kg C m<sup>-2</sup>  
557 yr<sup>-1</sup>). Still, they attributed the C losses to the recent conversion of grassland (with high SOC stock) to cropland (with  
558 low SOC stock), which may explain the doubled carbon stock change compared to this study.

559 The AMG model reproduced the observed SOC stock decline, though with a slightly greater magnitude, reinforc-  
560 ing the conclusion that the FR-Gri soil was not in carbon equilibrium and that a persistent negative C balance is  
561 the most plausible driver of SOC losses during that period (Figure 6). The model projections suggest that the SOC  
562 stock should decline at the same rate until 2027 before stabilising. A sensitivity analysis reveals that increasing  
563 the residue return would lead to a stabilisation of the SOC stock at 7.2 kg C m<sup>-2</sup>, compared to 6.95 kg C m<sup>-2</sup> under  
564 current management, while doubling the organic carbon amendment would result in an equilibrium of 7.5 kg C m<sup>-2</sup>.  
565 Conversely, suppressing organic carbon amendments, which may be close to reality with the installation of a  
566 biogas plant on the farm, would lead to a stabilisation of 6.3 kg C m<sup>-2</sup>. Although not explicitly simulated in our  
567 study, digestate residues from biogas production could serve as an alternative organic amendment. While this  
568 residue typically contains lower content of labile organic carbon compared to fresh organic material, the remaining  
569 organic material tends to be more chemically recalcitrant and resistant to microbial decomposition. As a result,  
570 their incorporation into the soil may contribute to slight but persistent increases in SOC stocks over time (Keel et  
571 al., 2025; Thomsen et al., 2013).

572 Finally, the integrated carbon fluxes from 2006 to 2010 (Loubet et al., 2011) confirm a carbon loss from the soil  
573 comparable to that simulated by the AMG model (Figure 6). Although the uncertainties in the integrated carbon  
574 fluxes are substantial, the convergence between the two approaches corroborates a significant soil carbon loss in  
575 the years 2005-2010, which is consistent with the decrease in organic carbon fertilisation and residue return during  
576 that period (Table 1) compared to previous years. We also note that the yearly carbon loss from Loubet et al.  
577 (2011) is not significantly different from the yearly carbon soil destocking found in the present study. In the north-  
578 western part of Switzerland, in a Cambisol soil, Leifeld et al. (2011) compared integrated carbon fluxes and soil  
579 sampling methods over 5 years on both an intensive and an extensive grassland that had been recently converted

580 from intensive cropland. They concluded that the significant uncertainties in both methods prevented the detection  
581 of a significant change over 5 years in the intensive field. On the contrary, in the extensive field, they found a  
582 significant decrease of the SOC stock of  $-0.217 \pm 0.143 \text{ kg C m}^{-2} \text{ yr}^{-1}$  by soil sampling, but a lower loss of  $-$   
583  $0.065 \pm 0.092 \text{ g C m}^{-2} \text{ yr}^{-1}$  based on the integrated carbon fluxes method.

### 584 **4.3 Uncertainties in soil carbon stock changes**

585 We recognise the importance of distinguishing an actual SOC stock change from artefacts introduced by differ-  
586 ences in sampling designs in 2005 and 2019. To address this, the clustering of the soil based on 2019 soil properties  
587 (See Supplementary Material and Methods, Figure S1) provides an objective way to subset the 2019 dataset  
588 for comparison with the 2005 campaign under similar soil conditions. The data-driven area selection corroborates  
589 the farmer's expert knowledge of the field heterogeneity. The robustness, across both design- and model-based  
590 approaches, alongside the clustering of soil properties to identify distinct soil groups, increases our confidence that  
591 the observed differences reflect fundamental changes in soil carbon stocks over time.

592 In the *Reduced field* (Figure S4), the observed SOC stock change between 2005 and 2019 in the 0-60 cm layer  
593 was  $-0.95 \pm 0.22 \text{ kg C m}^{-2}$ , exceeding the minimum detectable difference (MDD) of  $0.73 \text{ kg C m}^{-2}$  ( $p < 0.01$ ), and  
594 this represents both significant and detectable changes given our sample size and design. In contrast, the *Complete*  
595 *field* (Figure S4) did not exhibit the same pattern, as the observed SOC changes fell below the MDD, suggesting  
596 that the changes detected between 2005 and 2019 may have been masked by spatial heterogeneity. For these rea-  
597 sons, computations using the Complete field were not considered in this study, as they could lead to a Type II error  
598 (failing to detect a real effect). The larger MDD when all strata are included in our comparisons reflect increased  
599 soil heterogeneity, particularly related to the potential presence of Calcisol (shallow soil with high rock fragments  
600 and SIC content) on the north-western part of the field. These factors not only affect the soil bulk density and fine  
601 earth mass, but also the soil's capacity to stabilise carbon through positive interactions between Calcium (Ca) and  
602 soil organic matter (Kleber et al., 2021). These factors also lead to significant variability in biomass production,  
603 with the Calcisol area, which retains less water, being less productive, as observed by harvest maps (Loubet et al.,  
604 2011). This leads to fewer carbon inputs in this area through the return of residues to the soil.

605 Additional uncertainty on the overall SOC stock change at the site may come from inorganic carbon losses. Indeed,  
606 previous measurements of carbon leaching at the FR-Gri site indicated that inorganic carbon, whose stock change  
607 could not be evaluated with the 2005 sampling data, may also contribute to significant soil carbon losses. Kindler  
608 et al. (2011) showed that, in 2010, the site was losing  $28 \text{ g C m}^{-2} \text{ yr}^{-1}$  through leaching with a contribution of  
609  $21 \text{ g C m}^{-2} \text{ yr}^{-1}$  as dissolved inorganic carbon (DIC). Inorganic carbon leaching dominates at the site, with 75% of  
610 the leached carbon being inorganic, indicating an apparent dissociation of carbonates to DIC leaching due to  $\text{H}^+$ .  
611 Although not measured directly as a soil stock change, we can therefore evaluate that carbonate leaching would  
612 lead to an additional inorganic soil carbon loss of  $21 \text{ g C m}^{-2} \text{ yr}^{-1}$ , leading to a total of  $72 + 21 = 93 \text{ g C m}^{-2} \text{ yr}^{-1}$   
613 carbon loss. The inorganic carbon loss would therefore represent a very significant amount of 22% of the total  
614 carbon lost from the field, which could be induced by high nitrogen fertilisation ( $193 \text{ kg N ha}^{-1}$  as half organic,  
615 half mineral, Table 1) and base cations exports by harvest (Raza et al., 2021; Song et al., 2022; Zamanian et al.,  
616 2021). We should, however, bear in mind that even if C is lost by DIC-DOC leaching from the 0-60 cm layer, it  
617 may lead to a deep C sequestration by formation of secondary  $\text{CaCO}_3$  (An et al., 2019; Liu et al., 2022).

618 Based on the uncertainties identified in this study, several key points should be considered for the next resampling  
619 campaign to enhance the detectability of stock changes in SOC. First, maintaining consistency in the sampled area  
620 and sampling protocols (including material used for sampling) across campaigns is critical to avoid confounding  
621 temporal changes with spatial variability. Second, sampling depth should also extend sufficiently deep (1 m) as  
622 SOC losses and gains vary across the soil profile. Third, accurate quantification of bulk density, rock fragment  
623 content, and fine earth mass remains essential, and consistent protocols should be applied across campaigns to  
624 ensure compatibility with equivalent soil mass approaches. Finally, Consistent recording of meteorology, carbon  
625 fluxes, and C inputs and outputs, together with their uncertainties, is also key to interpreting the observations. The  
626 application of the ICOS harmonised protocols fulfils all the above-mentioned key points and ensures methodolog-  
627 ical consistency and comparability across years, particularly when using equivalent soil mass approaches. Some  
628 additional observations that are not mandatory in ICOS may be beneficial for further understanding soil carbon  
629 stock changes, particularly in terms of organic and inorganic carbon leaching. Together, these considerations will  
630 enhance the ability of future resampling campaigns to detect SOC stock changes robustly and distinguish between  
631 management and environmental-driven effects, as well as spatial and methodological sources of uncertainty.

## 632 **5 Conclusions**

633 A significant decompaction of the 0-5 cm soil layer was observed over the 13.25 years in this crop field, with an  
634 estimated 22% decrease in bulk density in the 0-5 cm layer and a 5% decrease in the 5-30 cm layer. This decom-  
635 paction is likely due to reduced deep tilling and increased intercropping since 2004. However, despite the higher  
636 SOC content in 2019, SOC stocks increased only in the 0-5 cm layer, while decreasing in the 5-30 cm layer, with  
637 no change in the 30-60 cm layer. Consequently, cumulative SOC stocks in the 0-60 cm layer decreased by  
638  $0.95 \pm 0.22 \text{ kg C m}^{-2}$ , as estimated by the equivalent soil mass approach. As we observed a similar decrease when  
639 using a fixed depth approach in the 0-60 cm layer, we conclude that sampling at a depth of 60 cm in agricultural  
640 soils is a good way to minimise biases in soil carbon stock evolution estimates.

641 The annual decrease of cumulative SOC stock was  $72 \pm 16 \text{ g C m}^{-2} \text{ yr}^{-1}$ , equivalent to a  $-0.65\% \text{ yr}^{-1}$  rate of decline.  
642 This rate is consistent with earlier studies and supported by the AMG model simulation and flux balance approach  
643 over the 2005-2010 period for our site. Our study, therefore, suggests that reduced tillage, intercropping, and  
644 organic fertilisation may not be sufficient to prevent soil carbon losses when the initial SOC stock is high, as in  
645 our site. As confirmed by other studies, the losses observed here highlight the difficulty of achieving the 4-per-  
646 mille aspirational target in cropping systems representative of the Parisian Basin, which are characterised by rela-  
647 tively large SOC stocks and significant exports.

648 While our study detected changes in SOC stock between 2005 and 2019, substantial uncertainties remain. Notably,  
649 the shift from a regular-grid design in 2005 ( $N = 100$ , nested within the 2019 footprint) to a stratified random  
650 design in 2019 ( $N = 20$  covering the entire C-flux footprint) may introduce artefacts related to soil heterogeneity  
651 and reduced statistical power. This calls for additional campaigns in the future with the same sampling design as  
652 in 2019. According to the AMG model runs, a change of around  $0.3 \text{ kg C m}^{-2}$  is expected between 2019 and 2028,  
653 which would be just above the standard error difference of  $0.22 \text{ kg C m}^{-2}$  found here, indicating that a sample in  
654 2028 would be meaningful.

655 These uncertainties call for standardised, high-quality monitoring protocols such as those developed by the ICOS  
656 research infrastructure. Consistent sampling methodologies over time are needed to reliably assess the long-term

657 impact of crop management on SOC stocks at sites like FR-Gri, and to improve our understanding of carbon  
658 dynamics in cropland systems. Integrating SOC stock data with CO<sub>2</sub> flux measurements and lateral carbon fluxes  
659 will be crucial to exploring the underlying processes driving SOC changes.

## 660 **Acknowledgements**

661 We acknowledge the AgroParisTech Grignon farm and its director, Dominique Tristant, for letting us access their  
662 field and providing information on practices and yields, the direction of the infrastructure of INRAE for funding  
663 the ICOS FR-Gri site, and EU projects CarboEurope, NitroEurope and ECLAIRE for funding this work. Data  
664 processing, including the sample analysis, was supported by the ICOS Ecosystem Thematic Centre. G.N. acknowl-  
665 edges Horizon Europe funding (Open-Earth-Monitor Cyberinfrastructure project, 101059548). D.P. thanks the  
666 support of the ITINERIS Project (IR0000032 - CUP B53C22002150006) funded under the EU - Next Generation  
667 EU Mission 4. B.W. thanks the support of the exploratory research program FairCarboN funded by the Agence  
668 Nationale de la Recherche under the France 2030 program, reference ANR-22-PEXF-0002 – project ALAMOD.  
669 We greatly acknowledge Marion Schrupf from the Max Planck Institute and her team for sharing the 2005 soil  
670 sampling data. We also thank Eric Larmanou for helping in the field during the soil sampling campaign in 2005.

## 671 **Code/Data availability**

672 The Level-2 data from the 2019 campaign are publicly available through the ICOS Carbon Portal (Buisse et al.,  
673 2025). The raw data from both sampling campaigns, all input files (including the complete R project), and the R  
674 scripts used for data processing and analysis are available in Winck et al. (2026).

## 675 **Authors contribution**

676 BL conceptualised, supervised, acquired the funding for the study and administered the project. BL and MG co-  
677 wrote the original draft of the manuscript with contributions from all co-authors and revised it. NS and BW pro-  
678 vided the formal analysis, provided the statistical expertise and scripts to compute the carbon stocks in the original  
679 manuscript, and co-wrote the manuscript. PB made the soil sampling and data curation for the 2019 campaign,  
680 curated the crop management data and reviewed the manuscript. JPC and NS participated in the ICOS database  
681 data curation. CD managed the soils storage in 2019, contributed to data curation, and reviewed the manuscript.  
682 CJ provided expertise on the soil sampling methodology. CK made data curation on the crop management data  
683 and reviewed the manuscript. FL computed the AMG and reviewed the manuscript. BW and JLME provided  
684 expertise on the ESM methodology and reviewed the manuscript. SL participated in data curation and reviewed  
685 the manuscript. DL and DP conceptualised the data acquisition and reviewed the manuscript. GN participated in  
686 the data curation. DA initiated the project, conceptualised, developed and provided expertise on the methodology  
687 and revised the manuscript.
