## S1. OH exposure estimation method in the Go:PAM flow tube

Experiments apply OFR254 mode of Go:PAM flow tube, where OH radical serve as the main oxidant. The OFR 254 mode generate OH radical from reaction of O(<sup>1</sup>D) radical and water vapor. O(<sup>1</sup>D) radicals are generated by photolysis of ozone<sup>1</sup>. The reactions are listed in RS1-RS3:

We estimate OH exposure in the flow tube using semi-empirical equation recommended by Peng et al<sup>2</sup> as shown in the main text. EqS1 represents the equation.

$$\log_{10} OH\ exposure(molecules\ cm^{-3}) = 15.514 + 0.79292 * \log_{10}[H_2O] + 0.023076 * (\log_{10}[H_2O])^2 - 1.0238 * \log_{10}[\Phi_{254}] + 0.060786 * (\log_{10}[\Phi_{254}])^2 - \log_{10}\{exp[-0.42602 - \log_{10}([O_3]/OHR) / 0.39479]\} + \log_{10}(t_R/180) \quad (Eq. S1)$$

In equation S1, [H<sub>2</sub>O] stand for dimensionless water vapor mixing ratio in the flow tube that is converted from relative humidity data. Φ<sub>254</sub> means total photon flux of the flow tube's ultraviolet lamp at 254nm. The Φ<sub>254</sub> in the Go:PAM flow tube used in the experiments are determined by comparison between photometer measurement and ozone blank experiment estimation, quantified to be 6.05×10<sup>15</sup> photons cm<sup>-2</sup> s<sup>-1</sup>. [O<sub>3</sub>] is ozone concentration in ppbv monitored by ozone analyzer. t<sub>R</sub> is retention time of the OFR that is 55 second in current study. OHR is total OH reactivity in the flow tube. OHR is estimated based on VOCUS-PTR quantification of gas-phase organic compounds. For compounds with certain elemental composition detected by VOCUS, we search organic species in the National Cancer Institute (NCI) database to find molecules with same elemental composition, and summarize OH reaction rate constants provided by EPI SUITE<sup>TM</sup>. We choose geometric mean of OH reaction rates provided by EPI SUITE<sup>TM</sup> as the rate coefficient corresponding to molecules with same elemental composition detected by VOCUS<sup>3, 4</sup>. Validation on applicability of equation S1 to our Go:PAM OFR is tested by sulfur dioxide-oxidation calibration experiment, using OH exposure result from SO<sub>2</sub> decay and a simple chemistry model<sup>5</sup> representing OH generation and decay in flow tubes. Reactions used in the chemistry model are shown in Table S1, while comparison

between OH exposures from equation S1, measured SO<sub>2</sub> decay and chemistry model are shown in Figure S1. Wall loss of primary aerosols is shown in Figure S2.

## S2. VOCUS & FIGAERO sensitivity/volatility calibration

For VOCUS data quantification, we utilize authentication standard gas mixture to calibrate the response of 25 VOCs in VOCUS with different composition and structure. Calibrations were

performed every day after the experiments finished at standard concentration 1, 10, 20 50, and 100ppbv. The standard gas includes 7 aromatic hydrocarbons (benzene, toluene, m-xylene, styrene, 1,2,3-trimethylbenzene, 1,3,5-trimethylbenzene, naphthalene), 5 terpenes and terpenoids (isoprene,  $\alpha$ -pinene,  $\beta$ -pinene,  $\beta$ -caryophyllene, nopinone), 5 carbonyl compounds (acetaldehyde, acrolein, acetone, methyl vinyl ketone, 3-pentanone, ethyl acetate), 3 alcohols (methanol, 2-propanol, 1-butanol), 2 nitriles (acrylonitrile, acetonitrile), and 2 halocarbons (chlorobenzene, 1,3-dichlorobenzene). For species detected with same elemental composition with any species among the standard gas, we choose the sensitivity of the compound in the standard standing for their sensitivity. For species detected having different elemental composition other than species in the standard gas, we divide species into elemental categories by having certain elemental abundant in the molecule (e.g. CH compounds, CHO compounds, CHON compounds) for convenience. We select the geometry mean sensitivity among compounds with same elemental category in the standard gas to represent the sensitivity of compounds in the whole group. The sensitivity data are used for OH exposure calculation<sup>7</sup>.

Quantification and volatility determination using FIGAERO-CIMS are completed utilizing calibration methods employed by Ylisirniö<sup>8</sup>. Schematic view of calibration process is shown in Fig S2 a). During sensitivity calibration, sensitivity of certain compound is determined by depositing certain volume of authentication standard solution onto PTFE filter inside FIGAERO inlet, and process one operation cycle with thermal desorption phase only. We choose acetonitrile as the solvent for better solvation and wetting ability on the filter. In the experiment, we deposit 3-5 different volume within the volume range 1 $\mu$ L -20 $\mu$ L of standard solution with concentration ~1 $\mu$ g/mL onto the filter, proceed the thermal desorption cycle, and count the target compound-iodide ion during the desorption process. Sensitivity of selected compound in CIMS is determined by equation S2:

$$\overline{([RI^-]/[I^-])} = S_i(ncps \cdot ppb^{-1}) \times V \times c \times \frac{RT}{pQ_{TD}\Delta t_{TD}} + \overline{([RI^-]/[I^-])}_{blank} \quad (\text{Eq. S2})$$

In Equation S2,  $[RI^-]/[I^-]$  stands for average normalized signal of selected compound during the thermal desorption process whose normalization based on reagent ion (iodide ion) signal,  $([RI^-]/[I^-])_{blank}$  for normalized signal during blank samples, V for total volume of standard solution deposited in  $\mu$ L, c for standard solution concentration in  $\mu$ g/mL, T for room temperature in Kelvin,

$p$  for atmospheric pressure in Pa,  $Q_{TD}$  for carrier gas flow rate during thermal desorption in  $m^3/min$ ,  $\Delta t_{TD}$  for thermal desorption duration in minutes. In calibration of this study,  $Q_{TD}$  is 0.002  $m^3/min$ , and  $\Delta t_{TD}$  is 45min, longer than 35min in experiment setup. The final sensitivities are given by linear regression between normalized signal  $[RI-]/[I-]$  and solution deposition volume  $V$ . For volatile compounds such as formic acid and acetic acid, calibration is completed by generating standard gas from penetration tube, then process linear fit between normalized ion counts and standard gas concentration.

For signals without corresponding standard compound and thus lack direct sensitivity calibration, we use 2-D VBS proxy to determine the sensitivity. Briefly, we put compounds detected by CIMS into 2-D VBS space using parameterization shown in Section S3. Then, we proceed k-means clustering algorithm built in MATLAB® on compounds in the 2-D VBS space, divide these compounds into several groups as shown in Fig. S3. Next, we distribute standard compounds with known sensitivity into 2-D VBS space, finding out each group's corresponding standard compound adapting KNN classification model from clustering results. Finally, we set the sensitivity of compounds having molecular formula different from all of the calibrated compounds to geometry mean sensitivity of standard compounds in the same group. These results could help improve characterization and quantification of species detected by CIMS by species and in 2-D VBS framework.

Volatility determination by FIGAERO is based on log-linear correlation between desorption temperature while signal reaches its peak<sup>9</sup>. Volatility calibrations is proceeded choosing polyethylene glycol (PEGs) as standard compound. Calibrations are proceeded following experiment setup in Fig. S2 b). Standard solution of PEGs is generated by dissolve PEG standard in acetonitrile, then atomized and deposited onto the filter. For other standard solution, we used same method as sensitivity calibration to achieve relation between desorption peak temperature. The result empirical log-linear relation between peak temperature  $T_{max}$  at room temperature and saturation vapor pressure  $p_0$  from PEGs are shown in Equation S3.

$$\log_{10} p_{0,298K} = 21.9 - 0.072T_{max}(K) \quad R^2 = 0.94 \quad (\text{Eq. S3})$$

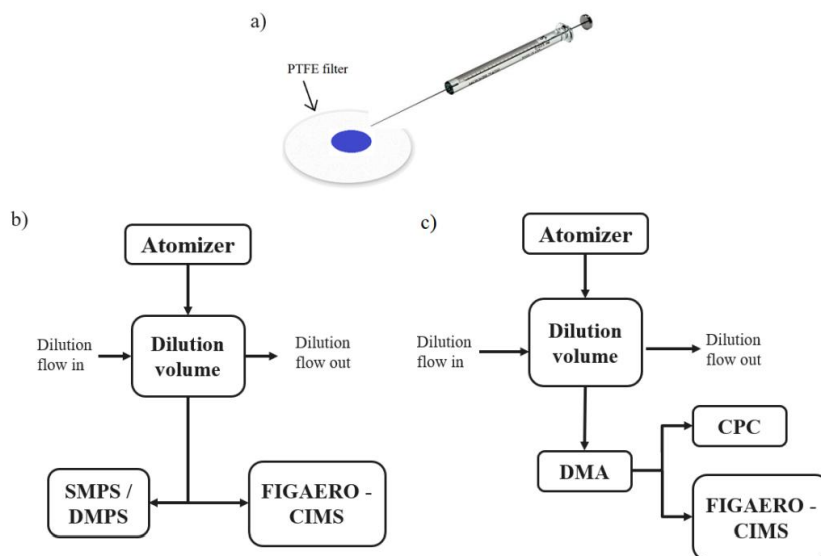

Figure S3 FIGAERO-CIMS volatility and sensitivity calibration method introduced by Ylisirniö, A., et al. (2021) that is used in this article. a) Illustration of the syringe deposition method. b) & c) Illustration of the polydisperse & monodisperse deposition method

Table S2 Sensitivity of calibrates used in CIMS sensitivity calibration and  $1\sigma$  confidence interval

Species	Molecular composition	Sensitivity (ncps ppb <sup>-1</sup> ) **
PEG-7	C <sub>14</sub> H <sub>30</sub> O <sub>8</sub>	$9.3_{9.0}^{11.2} \times 10^{-2}$

Figure S5 Correlation between FIGAERO thermal desorption peak temperature and saturation vapor pressure of PEGs and OOMs in previous and current studies<sup>8-15</sup>

## S3. 2-D VBS spacing

2-D VBS framework is firstly developed by Donahue in 2011<sup>16</sup>. The framework added Distribution of gas-phase and aerosol-phase organic compounds in 2-D VBS space are determined from molecular elemental composition detected by ToF-CIMS measurements. Parameterization used in this article is according to Li et al., as shown in Equation S4<sup>17</sup>:

$$\log_{10} C_0 = (n_C^0 - n_C)b_C - n_O b_O - 2 \frac{n_C n_O}{n_C + n_O} b_{CO} - n_N b_N - n_S b_S \quad (\text{Eq. S4})$$

In Eq. S4, targeted saturation vapor concentration  $C_0$  is determined by elemental composition and semi-empirical parameters.  $n_C$ ,  $n_O$ ,  $n_N$ ,  $n_S$  are number of most abundant elements atmospheric in organic aerosols,  $n_C^0$  stand for reference carbon number,  $b_C$  means influence of molecular size on volatility,  $b_O$ ,  $b_N$ ,  $b_S$  shows effect of functional group containing O, N, and S atom,  $b_{CO}$  means polar- nonpolar interaction influence on volatility. Parameters used for compounds with different molecular composition given by Li et al. are shown in Table S3.

Table S3 Elemental composition class and corresponding parameters in Eq. S4

Elemental Composition Class	$n_C^0$	$b_C$	$b_O$	$b_{CO}$	$b_N$	$b_S$
CH	23.8	0.4861	--	--	--	--
CHO	22.66	0.4481	1.656	-0.7790	--	--

CHOS	24.06	0.3637	1.327	-0.3988	0	0.7579
CHONS	28.5	0.3848	1.011	0.2921	1.053	1.316

## S4. Non-targeted analysis utilizing matrix factorization analysis

For complex mass spectrometry data, non-targeted analysis is introduced to achieve

characteristics quantities of detected species without reliable direct prior compound and structure information. Basic concept and data-process path are shown in Figure S6<sup>18</sup>. Matrix Factorization approaches has been introduced as crucial methods in non-targeted analysis. Briefly, Matrix Factorization is a dimension reduction approach that approximately divide a target  $m \times n$  data matrix  $\mathbf{X}$  containing hundreds of variables( $n$ ) and change through hundreds of time points( $m$ ) into  $p$ (unknown) different constant sources that varies with time, as shown in Equation S5. The source composition profile are shown in a  $n \times p$  matrix  $\mathbf{F}$ , while the time series of the source are in the  $m \times p$  matrix  $\mathbf{G}$ . Factorization target is to cover the difference between data matrix  $\mathbf{X}$  and fitted matrix  $\mathbf{R}$ , minimizing the error matrix  $\mathbf{E}$  toward the measurement uncertainty matrix  $\sigma$  of input data.

$$\mathbf{X} = \mathbf{GF} + \mathbf{E} = \mathbf{R} + \mathbf{E} \quad \text{Eq. S5}$$

For a better factorization result, we compared two widely used factorization approaches for high-resolution mass spectrometry factor analysis processes: Multilinear Engine-2 Positive Matrix Factorization (ME-2 PMF) and Non-Negative Matrix Factorization (NNMF)<sup>19</sup>. ME-2 PMF is proceeded by utilizing Igor Pro<sup>®</sup> program SoFi<sup>®</sup> developed by Canonaco et al.<sup>20</sup>. NNMF is proceeded by built-in algorithm in MATLAB<sup>®</sup><sup>21</sup>. To achieve better deconvolution result, and to avoid possible background signal interference or physical unreasonable factorization results, we also proceed three different data pre-treatment methods on input matrixes. These includes direct factorization of full time series data without further selection and pre-treatment other than basic data pre-treat methods developed by Buchholz et al.<sup>22</sup>, normalize time series data to maximum for trend analysis, and particle-phase only data for volatility & oxidative state analysis. The Goodness of PMF and NNMF results are evaluated by global and local evaluation parameters. Global evaluation parameters include  $Q/Q_{exp}$ , root mean square error (RMSE), explained absolute variance  $Ratio_{var}$ , focusing on performance on the whole data set. Local parameters include time series of summed absolute relative residual and unexplained variation (UEV) among all ions<sup>20, 22</sup>. These parameters are defined below:

$$Q = \sum_{j=1}^m \sum_{i=1}^n \left( \frac{E_{ij}}{\sigma_{ij}} \right)^2 \quad Q_{exp} = n \times m - p \times (p + m) \quad \text{Eq. S6}$$

$$RMSE = \sqrt{\frac{\sum_{j=1}^m \sum_{i=1}^n (E_{ij})^2}{n \times m}} \quad \text{Eq. S7}$$

$$Ratio_{var} = \frac{\sum_{ij}|R_{ij}-\bar{X}_i|}{\sum_{ij}|R_{ij}-\bar{X}_i|} \quad \text{Eq. S8}$$

$$\text{Sum relative residual}_i = \frac{\sum_j R_{ij}-X_{ij}}{\sum_j |X_{ij}|} \quad \text{Eq. S9}$$

$$\text{absolute relative residual}_i = \frac{\sum_j |R_{ij}-X_{ij}|}{\sum_j |X_{ij}|} \quad \text{Eq. S10}$$

$$UEV_i = \frac{\sum_j |e_{ij}/\sigma_{ij}|}{\sum_j |X_{ij}/\sigma_{ij}|} \quad \text{Eq. S11}$$

To obtain a reasonable result, UEV are expected to be less than 25%.  $Q/Q_{\text{exp}}$  are targeted to reduce to near 1. For best factor number, we firstly plot the relation between factor number and global goodness parameters, choose the “turning points” where goodness parameters decrease significantly slower after the point than before, which means the factor number is most efficient. Then, we examine the time series of local goodness parameters at and just after “turning points” to investigate if adding factor number at the turning point leading to significant developments of factorization result. Next, we look at thermogram during thermal desorption in FIGAERO operation, and finally choose reasonable factorization results. Global and local parameters are also used for determination of PMF&NNMF performance on proceeding factorization and thus choosing suitable factorization method and data pre-treat methods for CIMS data processes. Spectra contrast angle  $\theta$  are used to assign the similarity of factors, treating spectra of each factor as vectors in linear space make up by species concentration<sup>22, 23</sup>. Determination of contrast angle are shown in Equation S12:

$$\cos\theta = \frac{\sum_i a_i b_i}{\sqrt{\sum_i a_i^2 \sum_i b_i^2}} \quad \text{Eq. S12}$$

In Equation S12,  $a_i$  and  $b_i$  stands for spectra intensity of different factors in MPF results. Two factors would be considered not similar if  $\theta > 30^\circ$ <sup>24</sup>. Thus, a good PMF result should output factors with contrast angle  $\theta > 30^\circ$  between every two factors<sup>22</sup>.

Figures S7-S9 show change of the global goodness parameters of ME-2 PMF and MATLAB<sup>®</sup> NNMF while adding factor number. MATLAB<sup>®</sup> NNMF performed better regarding global goodness parameters not considering measurement uncertainty such as lower RMSE and higher  $Ratio_{var}$  especially at factor numbers below 10. However, while considering relationship between measurement uncertainty and factorization result bias using the  $Q/Q_{\text{exp}}$  parameter, ME-2 PMF

shows better performance. ME-2 PMF aim at minimize firstly the uncertainty of signal with lower measurement uncertainty, so the absolute relative residual time series of ME-2 PMF shows better performance than MATLAB® NMF at relevant factor number of both factorization methods, as Figures S10-S12 depicted. The two methods have comparable bias only when data pre-treat method are selected to be normalizing the time series of detected ions to its maximum value, which mainly aiming at extracting changing patterns, and thus expect to resolve volatility of detected species. Among data processes, while utilizing ME-2 PMF as the factorization algorithm, as Figures S13-S15 show, full time-series data shows slightly better performance than particle-phase only data and obvious advantage over time series normalized to maximum point of each detected compound. On the contrary, MATLAB® NMF method favors data process adopting normalized full time series than particle-phase only and full time series, especially at duration corresponding to measurement of primary cooking emissions, shown in Figures S16-S18. In conclusion, we would prefer choosing ME-2 PMF as factorization algorithm, select full time series data as main data pre-treat method factorization in this article, while compare results of particle-phase only data to volatility and partitioning results as reference. Table S5 shows contrast angle  $\theta$  between factors of ME-2 PMF best results. The contrast angles are between every two factors are larger than  $30^\circ$  (minimum  $35^\circ$ ), showing reasonable results of ME-2 PMF.

The factors obtained from PMF are classified with oxidative state and volatility. First, the 13<sup>th</sup> factor is considered contaminant factor, named Factor Unknown. The contamination factor consists of 3 separated peaks at totally separate desorption temperatures, implying that it may consist of three parts related to different interference. First part at low desorption temperature may contain interference from FIGAERO inlet model shifting that may mix gas-phase components with aerosol-phase, which can be observed at the first couple of seconds of particle phase data. Next two parts at higher desorption temperature may come from residuals of semi-volatile and low-volatile residuals. 12 interpretable factors are classified as 3 categories, considering its volatility represented by FIGAERO-CIMS measured gas-particle partitioning coefficient  $K_p$ . Factors mainly or even almost present in gas phase are named volatile factors “Vx”, factors abundant in both gas phase and aerosol phase factors are called semi-volatile factors “SVx”, and mostly particle phase factors are classified low-volatile factors “LVx”. Factors among each volatility categories are further distinguished and numbered by its oxidative state. Lower number

in factor name such as Factor V1 and SV1 are related to primary components, while reaching higher abundance at low oxidative states. Medium number factors, namely Factor V2LV1 and SV2, correspond to intermediate oxidative states, consist of first-generation products. Factors with number  $\geq 3$  in their name represent highly oxidated products that relate to multi-generation oxidation.

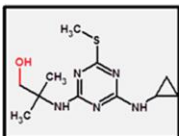

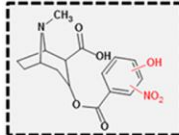

Example	Identification confidence	Minimum data requirements
	<b>Level 1: Confirmed structure</b> by reference standard	MS, MS <sup>2</sup> , RT, Reference Std.

Figure S22

## S5. Gas-particle partitioning theme

Volatility and gas-particle partitioning thermodynamics of organic compounds detected by FIGAERO-CIMS are processed by gas-phase and aerosol-phase concentration. Direct gas-particle partitioning characteristics are shown by particle-phase fraction  $F_p$ :

$$F_{p,i} = \frac{c_{p,i}}{c_{g,i} + c_{p,i}} \quad \text{Eq. S13}$$

In Equation S13,  $c_{p,i}$  stands for particle phase concentration of substance  $i$ ,  $c_{g,i}$  means gas phase concentration. Partitioning coefficient  $K_p$ , considering influence organic aerosol as matrix of substance  $i$ , is defined in Equation S14:

$$K_{p,i} = \frac{c_{p,i}/c_p}{c_{g,i}} \quad \text{Eq. S14}$$

In Equation S14,  $c_p$  means total particle concentration.  $F_p$  and  $K_{p,i}$  can be derived from FIGAERO-CIMS and other corresponding measurement results. detection of certain ion (iodide adduct ion  $[RI^-]$  or hydrogen extraction ion  $[R-H]^-$ ) corresponding to species  $R$ , particle-phase thermal desorption duration and flow rate  $\Delta t_{TD}$  &  $Q_{TD}$ , collection duration and flow rate  $\Delta t_{col}$  &  $Q_{col}$ , average SMPS-measure particle concentration  $c_{p,SMPS}$ , shown in Equation S15-S16:

$$(F_{p,i})_{exp} = \frac{\overline{([RI^-]/[I^-])}_{aero} \cdot Q_{TD} \cdot \Delta t_{TD}}{[\overline{([RI^-]/[I^-])}_{gas} \cdot Q_{col} \cdot \Delta t_{col} + (\overline{([RI^-]/[I^-])}_{aero} \cdot Q_{TD} \cdot \Delta t_{TD})} \quad \text{Eq. S15}$$

$$(K_{p,i})_{exp} = \frac{\overline{([RI^-]/[I^-])}_{aero} \cdot Q_{TD} \cdot \Delta t_{TD}}{[\overline{([RI^-]/[I^-])}_{gas} \cdot Q_{col} \cdot \Delta t_{col}] \cdot c_{p,SMPS}} \quad \text{Eq. S16}$$

Eq. S15 and S16 can be used to classify PMF factor from volatility angle by substituting intensity of certain compound  $[RI]/[I]$  with intensity of one factor. Gas-particle partitioning in POA and SOA mainly follows absorption mechanism<sup>25, 26</sup>, where species exist in aerosol phase at liquid-solution state.

Considering the mechanism of absorption partitioning,  $F_p$  is related to mass of total particle phase organics  $c_{OM}$ , shown in Equation S17<sup>27</sup>, while  $K_p$  only depends on properties of species  $i$  and particle phase composition. Assuming gas-particle partitioning of component  $i$  reaches its equilibrium, partitioning coefficient  $K_{p,i}$  is determined by organic aerosol composition and volatility of compound  $i$  as shown in Equation S18:

$$(F_{p,i})_{theo} = \left(1 + \frac{c^*}{c_{OM}}\right)^{-1} \quad \text{Eq. S17}$$

$$(K_{p,i})_{theo} = \frac{RTf_{OM}}{MW_{OM}p_{L,i}^0\xi_i} \quad \text{Eq. S18}$$

In Eq. S18,  $f_{OM}$  means fraction of organic part in aerosols, which is set to 1 in this study.  $MW_{OM}$  stands for mean molecular weight among all species in organic aerosol.  $p_{L,i}^0$  means saturated vapor pressure of component  $i$  over liquid pure component surface.  $\xi_i$  means activity coefficient in particle phase. Assuming  $\xi_i$  as close to unity, the volatility of component  $i$  can be determined from gas-particle partitioning of component. If we are able to classify the exact structure from possible reaction path during oxidation of utilize estimation method of volatility from corresponding compound detected by CIMS such as SIMPOL & EVAPORATION<sup>28, 29</sup>. We could also adopt 2-D VBS approach listed in Section S3 to calculate volatility of certain species, which may lead to larger bias. Volatility of species  $i$  can be also determined by thermogram from thermal desorption measurements of particle phase according to methods mentioned in section S2<sup>30, 31</sup>, which may be more accurate than partitioning method due to possible interference such as thermal desorption<sup>32</sup>. After the volatility has been obtained, activity coefficient  $\xi_i$  can be briefly determined so as to account for composition influence on gas-particle partitioning and possible kinetic effects.

Gas-particle partitioning of organic species may not reach equilibrium because of kinetic limitations. Gas-particle partitioning kinetics consist of gas phase diffusion, surface accommodation and particle-phase diffusion processes, the kinetics are determined by gas-phase diffusion coefficient  $D_{g,i}$ , surface accommodation coefficient  $\alpha$ , and particle-phase diffusion coefficient  $D_{p,i}$ . Gas phase diffusion coefficient of species  $i$  in real atmosphere can be calculated from elemental composition of selected species from Fuller's method:

$$D_{g,i} = \frac{1.0868 \times T^{1.75}}{p \cdot \sqrt[3]{m(i,A)} \cdot (\sqrt[3]{V_A} + \sqrt[3]{V_i})^2} \quad \text{Eq. S19}$$

In equation S19,  $D_{g,i}$  is in  $\text{cm}^2 \text{s}^{-1}$ ,  $T$  and  $p$  is atmospheric temperature and pressure in Kelvin and Torr,  $m(i,A)$  means reduced molar mass of species  $i$  and ambient air in g/mol,  $V_i$  and  $V_A$  are molecular diffusion volume of ambient air and selected species  $i$ , which can be directly estimated by elemental composition. Most organic species involved in gas-particle partitioning have diffusion coefficient within  $10^{-2}$  to  $10^{-1} \text{cm}^2 \text{s}^{-1}$  level<sup>33</sup>. Particle phase diffusion  $D_{p,i}$  are connected particle phase viscosity  $\nu$ , shown in Equation S20 (Stokes-Einstein Equation)<sup>34</sup>:

$$D_{p,i} = \frac{kT}{6\pi a \nu} \quad \text{Eq. S20}$$

In Eq. S20,  $k$  is Boltzmann constant,  $T$  is particle-phase temperature,  $a$  means effective molecular diameter in molecular diffusion, which are at the level of several Å<sup>35, 36</sup>. Particle-phase viscosity can be parameterized by composition distribution in 2-D VBS space that has been detailed discussed<sup>37</sup>. Gas-particle partitioning kinetic can thus be estimated by time scale of gas-phase diffusion and particle-phase diffusion. Gas-phase and particle-phase diffusion characteristic time scale  $\tau_{g,i}$  and  $\tau_{p,i}$  are shown in Equations S21-S25<sup>34, 38</sup>:

$$\tau_{g,i} = 1/k_{gp,i} \quad \text{Eq. S21}$$

$$k_{gp,i} = \sum_p 4\pi D_{g,i} r_p N_p \beta \quad \text{Eq. S22}$$

$$\beta = \frac{0.75\alpha(1+Kn)}{Kn^2 + Kn + 0.283Kn\alpha + 0.75\alpha} \quad \text{Eq. S23}$$

$$Kn = \frac{3D_{g,i}}{\omega r_p} \quad \text{Eq. S24}$$

$$\tau_{p,i} = \frac{d_p^2}{4\pi^2 D_{p,i}} \quad \text{Eq. S25}$$

In Equations S21-S25,  $r_p$  is particle radius,  $d_p$  is diameter and  $N_p$  is particle number concentration at certain diameter range, measured by SMPS;  $\beta$  is correction factor adjusting surface accommodation related to Knudsen number  $Kn$ ,  $\omega$  is mean thermal velocity of species  $i$ . Comparison between  $\tau_{g,i}$ ,  $\tau_{p,i}$  and retention time in Go:PAM  $t_R(55\text{s})$  give us insight into gas-particle partitioning dynamics in the experiment.

## S6. Additional results
