

Text S1. ECCO-Darwin Southern Beaufort Sea configuration

ED-SBS is extracted and modified from the ECCO-Darwin global-ocean biogeochemical state estimate Carroll et al. (2020, 2022). Simulated ocean and sea-ice dynamics are based on the ECCO LLC270 global configuration Zhang et al. (2018) and coupled online with the Darwin ocean ecology and biogeochemistry model Dutkiewicz et al. (2013); Follows et al. (2007). The model
5 simulates the SBS ocean-sea ice-biogeochemical conditions on a curvilinear grid with a horizontal grid spacing ranging from 12–15 km. The water column is composed of 46 telescoping vertical levels, ranging from 3-m thick near the surface to 360-m thick near the seafloor Bertin et al. (2025). The biogeochemical component of the model explicitly simulates the cycling of carbon, nitrogen, phosphorus, silica, iron, and oxygen, transitioning between inorganic, living, and dead organic pools, including the carbonate cycle Follows et al. (2006). In ED-SBS, four plankton functional types (PFTs) representative of ecosystems
10 in the AO (diatoms, large eukaryotes, and small and large zooplankton) are explicitly simulated, along with phytoplankton Chl concentrations. Initial and boundary conditions for ocean, sea ice, and biogeochemical tracers were derived from the ECCO-Darwin global-ocean biogeochemical estimate Carroll et al. (2020), except for marine DOC, which was obtained from previous ED-SBS simulations Bertin et al. (2025).

15 Text S2. CDOM initial and boundary conditions

We generate CDOM initial conditions in two steps. First, we ran the ED-SBS model for 3 years with CDOM initial/boundary conditions set to zero and without river discharge. Over the three year model spin-up, the CDOM field was populated with non-zero values due to ecosystem dynamics (i.e., plankton growth, grazing, and mortality).

20 For phase two, we extracted CDOM boundary conditions from year-3 of the phase-one simulation described above. A spatial-mean CDOM vertical profile was computed for each open boundary (taken 5 grid cells away from the boundary to prevent zero values), resulting in mean boundary condition profiles for the west and east boundaries for an entire year. We then ran the phase-two simulation for 5 years with these repeat-year boundary conditions, initial conditions for CDOM set to zero, and included river discharge. We then used the last daily field of the phase-two simulation as CDOM initial conditions in our
25 final simulation. CDOM boundary conditions for the final simulation are the same as in phase-two simulation.

Text S3. Comparison metrics

We used 4 comparison metrics to compare retrieved CDOM absorption ($a_{CDOM}[\lambda]$) from simulated CDOM (hereafter X_{mod}) against observations (hereafter X_{obs}): the median (\pm standard deviation), the correlation coefficient (r), the median
30 percent error (MPE) and the unbiased root-mean-square error (URMSE). We calculated the correlation coefficient (r), the unbiased Root Mean Square Error (URMSE), and the Median Percent Error (MPE) as follows:

$$r = \frac{\sum[(X_{obs} - \overline{X_{obs}}) \cdot (X_{mod} - \overline{X_{mod}})]}{\sqrt{\sum(X_{obs} - \overline{X_{obs}})^2 \cdot \sum(X_{mod} - \overline{X_{mod}})^2}}, \quad (1)$$

$$URMSE = \sqrt{\frac{\sum[(X_{mod} - X_{obs}) - (\overline{X_{mod}} - \overline{X_{obs}})]^2}{n}}, \quad (2)$$

35

$$MPE = Median \left(100 \cdot \left| \frac{X_{mod} - X_{obs}}{X_{obs}} \right| \right). \quad (3)$$

The URMSE measures the size of the discrepancies between the simulated and observed values. The MPE is the median of the absolute percentage error and provides insights on the regression model accuracy.

Figure S1. Annual-mean sea-surface salinity simulated by ED-SBS. The black dotted line indicates the 27 isohaline (boundary of the Mackenzie River plume) and red markers show location of Malina campaign stations.

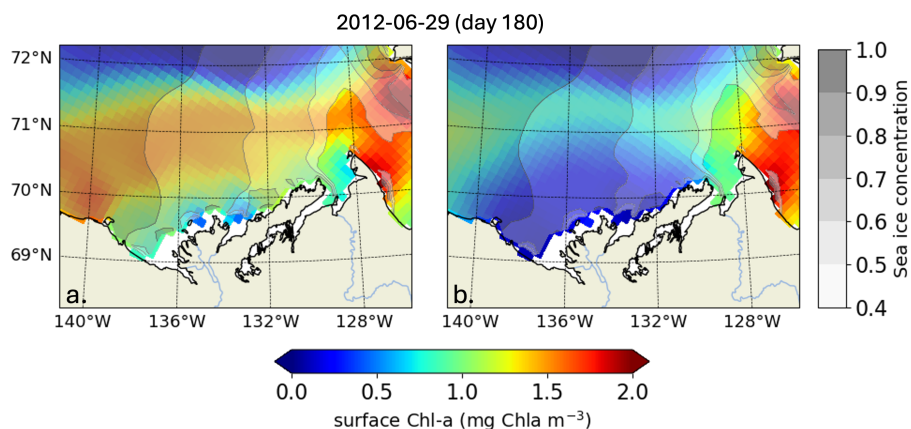

Figure S2. Simulated surface-ocean Chl-a concentration and sea-ice concentration for 2012-06-29 (a) without and (b) with the CDOM tracer effect.
