Abstract. Air pollution poses an increasing public health risk in many African cities, where systematic monitoring is limited 15 by the high cost of reference-grade instrumentation. Satellite-based sensors such as TROPOMI on Sentinel-5P provide global coverage of atmospheric pollutants, including nitrogen dioxide (NO_2), but their limited vertical resolution complicates the estimation of surface-level concentrations.

Palmes diffusion tubes offer a low-cost, low-tech alternative for measuring NO_2 at the ground level. Combining satellite 20 observations with data from ground-based diffusion tubes presents a promising approach for generating regional air quality maps, particularly in resource-limited settings. This study reports on the implementation of a pilot network of Palmes tubes in Kumasi, Ghana. To ensure sustainability and scalability, a local air quality laboratory was established to prepare and analyse the tubes using locally sourced materials and equipment.

Validation against tubes prepared and analysed by an accredited external laboratory demonstrated satisfactory agreement. Measurements from March 2025 revealed a wide range of NO_2 concentrations, from an average of $7 \mu\text{g m}^{-3}$ in residential 25 areas away from traffic and industry to peak values of $88 \mu\text{g m}^{-3}$ at heavily trafficked intersections—substantially exceeding the WHO 2021 guideline limits of $25 \mu\text{g m}^{-3}$ for 24-hour exposure and $10 \mu\text{g m}^{-3}$ for annual mean concentrations.

Averaged satellite data showed the accumulation of NO_2 plumes downwind of the city, though the relationship with surface-level measurements remains complex and needs further investigation. Column-to-surface ratios in Kumasi are significantly lower than those typically observed in European cities. TROPOMI underestimates the tropospheric NO_2 column densities by 30 a factor of roughly 2.5 in March 2025, as the higher aerosol loading over Ghana reduces retrieval sensitivity in the troposphere, increasing the reliance on unrepresentative *a priori* profiles.

1 Introduction

Ambient air pollution, in combination with household air pollution, is recognized by the World Health Organization (WHO) as a major global health threat, contributing to an estimated 6.7 million premature deaths each year. These deaths are 35 primarily attributed to chronic health conditions such as cardiovascular diseases, respiratory disorders, and lung cancer, all of which reduce life expectancy (WHO, 2023).

Among the major air pollutants, nitrogen dioxide (NO_2) is of particular concern (Wang et al., 2024). It is primarily produced through high-temperature combustion processes (Koziel et al., 2024), including emissions from vehicles, power generation, industrial operations, and various forms of biomass and waste burning (Huang et al., 2015; Qi et al., 2024; Wang et al., 2022; 40 Chong et al., 2024). Prolonged exposure to elevated NO_2 levels has been associated with respiratory illnesses such as bronchitis and emphysema, as it irritates the mucous membranes in the respiratory tract (Dons et al., 2018; Kim et al., 2020; Filonchyka et al., 2025). Additionally, NO_2 plays a key role in atmospheric photochemical reactions that produce tropospheric ozone (O_3) (Stržík et al., 2016; Jin et al., 2023; Chameides et al., 1994), a pollutant which is also linked to respiratory diseases, especially aggravation of asthma in asthmatic patients (De Vries, 2021).

45 Beyond its impacts on human health, NO_2 also contributes to environmental degradation. High concentrations have adverse impacts on the growth of vegetation and agricultural crops through acid rain, and which may lead to reductions in crop yield in high concentration areas (Van der Eerden and Duym, 1988).

In line with broader demographic trends across the African continent, Ghana—one of West Africa's leading economies—has undergone rapid population growth, with its population rising from approximately 25 million in 2010 to an estimated 35 50 million by 2025 (UN, 2024). During the same period, the urbanization degree increased from 50% to 59%. This rapid urban expansion, coupled with growing transportation and industrial activity, has likely led to increasing levels of air pollution, particularly in urban centres.

According to WHO (2025) health statistics, stroke, ischemic heart disease, and lower respiratory infections are among the leading causes of death in Ghana—conditions that are strongly linked to long-term exposure to air pollution. To better 55 understand and address these health burdens, localized and reliable data on air pollutant concentrations is urgently needed.

Continuous monitoring of ambient NO_2 is essential to inform effective policy and public health responses (Takte et al., 2023; Ling et al., 2025). Dense measurement networks are preferred (Bi et al., 2020; Gao et al., 2015; Huang et al., 2022; Schneider et al., 2017; Fua et al., 2023) as concentrations vary strongly over space, especially near emission sources such as traffic and industrial zones. Globally, thousands of regulatory air quality monitoring stations (AQMs) provide NO_2 data on 60 hourly basis. However, the high costs of establishing and maintaining these stations limit their deployment, even in high-income countries. To the best of our knowledge, there are currently no operational AQMs openly reporting NO_2 measurements in Sub-Saharan Africa (OpenAQ, 2025).

Alternatively, air pollution levels can be measured using low-cost air quality sensors (LCSs). Most active LCSs for NO_2 , however, rely on electrochemical sensing elements, which are susceptible to cross-sensitivity with other reactive gases and

65 are strongly influenced by temperature and humidity (Li et al., 2021; WMO, 2024). Their sensitivity can drift over the course of only few weeks (Mijling et al., 2018), necessitating a regular recalibration strategy—ideally performed alongside an AQM.

Passive samplers, such as Palmes diffusion tubes (PDTs), have been in use since 1976 (Palmes et al., 1976). These cost-effective devices are widely employed by environmental agencies to monitor NO₂, particularly in areas that are otherwise 70 undersampled (Medlanda et al., 2025). Their low-cost and low-tech nature makes them well-suited for continuous monitoring across the African continent. Although passive samplers have been deployed in temporary monitoring campaigns in cities such as Accra, Ghana (Wang et al., 2022), reliance on remote (often foreign) laboratories for the preparation and analysis of the samplers has posed a significant barrier to sustained, long-term monitoring.

To address this limitation, this study presents the development and first deployment of a locally managed and operated air 75 quality laboratory at Kwame Nkrumah University of Science and Technology (KNUST) in Kumasi, Ghana's second-largest city. The facility enables local preparation, deployment, and analysis of NO₂ diffusion tubes, supporting sustainable, cost-effective, and regionally scalable air quality monitoring.

In-situ measurements of NO₂ are essential for a better interpretation of satellite-based measurements. Polar-orbiting satellite instruments such as TROPOMI use remote-sensing techniques to determine column concentrations of NO₂ worldwide. 80 However, without ground-based validation, the relationship between these column measurements and surface-level concentrations remains uncertain. A better understanding of this connection is key to use satellite data in the monitoring of regional surface concentrations.

The remainder of this paper is organized as follows: Section 2 describes the materials and methods used, including details of 85 the diffusion tube deployment, laboratory procedures, and data analysis techniques. Section 3.2 presents the first in-situ NO₂ measurement campaign conducted in Kumasi. Section 3.3 evaluates the performance of the KNUST laboratory in comparison to an accredited reference lab. Finally, Section 4 compares the ground-level measurements with satellite-derived NO₂ columns to explore potential synergies for regional monitoring.

2 Material and methods

2.1 Palmes diffusion tubes

90 The measurement principle of a Palmes tube (Fig. 1) is based on molecular diffusion. The tube contains two fine stainless-steel grids impregnated with triethanolamine (TEA), a reagent that chemically binds NO₂ upon contact, forming nitrate (NO₂⁻). Diffusion takes place as there is a concentration difference between the open bottom of the tube (at ambient NO₂ concentration) and the closed top (at zero concentration). After exposure, the tube is sealed and brought to the laboratory, where the accumulated nitrate on the grids is quantified through chemical analysis. This mass is then used to calculate the 95 average ambient NO₂ concentration at the sampling site over the exposure period. Due to the slow diffusion rate, PDTs are

typically deployed for a four-week sampling duration. Shorter intervals, such as two weeks, are feasible but result in an increased measurement uncertainty.

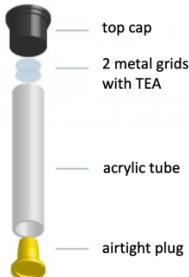

Figure 1: Components of the diffusion tube used in this study

100 **2.2 Kumasi NO₂ monitoring network**

Kumasi is the capital of the Ashanti Region in southern Ghana and serves as a major metropolitan and commercial hub. As of 2024, the city has an estimated population of approximately 3.5 million, making it the second-most populous city in Ghana. Geographically, Kumasi is situated at approximately 6.69° N latitude and 1.62° W longitude, at an elevation of about 250 to 300 meters above sea level. The city experiences a tropical rainforest climate, characterized by high humidity and 105 relatively stable temperatures throughout the year, ranging between 21°C and 31°C. Kumasi has a bimodal rainfall pattern, with major rains typically occurring from March to July, and a shorter rainy season from September to November. Annual rainfall averages between 1,300 mm and 1,500 mm. The dry season, associated with the Harmattan winds, usually spans December to February, though residual precipitation may occur.

We strategically selected 20 monitoring sites across Kumasi to capture the spatial variability of NO₂ pollution, such as high-110 traffic areas around marketplaces, health care sensitive zone such as hospitals, major industrial locations, and some urban background areas (Table 1). This categorization was intended to reflect the range of anthropogenic activities contributing to NO₂ emissions within the city and to assess potential exposure risks to different population groups. The location and classification of the sites is shown in Fig. 2.

115 **Table 1: Sites in Kumasi where Palms diffusion tubes were deployed along with their coordinates**

Location ID	Name	Type	Latitude	Longitude	Description
KU-001	Casley Hayfort T-junction	Traffic	6.67473	-1.56743	Busy junction on campus with bus stops where KNUST shuttle stops
KU-002	Kotei Road Junction (Ayeduase)	Traffic	6.67585	-1.55884	Busy junction on a small road close to campus, with little sidewalk shops around
KU-003	Tech Junction (KNUST hospital side)	Traffic / Hospital	6.68675	-1.57425	Very busy place with busy road coming from Accra, one of the main junctions in the city

KU-004	Krank High Business (Olam)	Industrial	6.64868	-1.60946	In the corner outside the factory, mainly busy with trucks and waste collectors
KU-005	Guinness Brewery	Industrial	6.65128	-1.60650	Next to the entrance to the Guinness factory, on the other side of plastic bottles waste collection
KU-006	Kumasi City Mall Roundabout	Traffic	6.67169	-1.60557	In the turn to enter the mall car parking, semi busy area
KU-007	Asafo Market	Traffic / Marketplace	6.68936	-1.61513	Important junction along Accra Road
KU-008	Kejetia Market Roundabout	Traffic / Marketplace	6.69734	-1.62196	Very busy place with the biggest market in West Africa next to it
KU-009	Adum Prison	Traffic	6.69433	-1.62331	Semi-busy roundabout, ending of the market
KU-010	Hospital KATH	Residential / Hospital	6.69602	-1.62761	Calmer area behind the hospital parking lot, emergency generator nearby
KU-011	Patasi Roundabout (Santase)	Traffic	6.67239	-1.64117	Busy roundabout with one main road crossing, tubes inside the roundabout area, green roundabout
KU-012	Ahoydo Roundabout (Ahodwo)	Traffic	6.66929	-1.61758	Tubes inside the green roundabout area, connecting residential area, in front of gas station
KU-013	Sofoline Interchange	Traffic	6.69999	-1.65053	In between the two directions of a highway
KU-014	Suame Circle	Traffic	6.71111	-1.62729	Dusty roundabout, tubes in the side of the roundabout close to where minibuses stop
KU-015	Airport	Traffic	6.70878	-1.59893	Closest roundabout to the airport entrance, a river nearby, in the gas station area
KU-016	Kings Palace (Manhyia)	Residential	6.70431	-1.61194	Between the King's palace entrance and the roundabout, on the outer part of the garden
KU-017	Ashawase	Traffic	6.69840	-1.59455	In the sidewalk of a big two-directional road
KU-018	Accra Road (Anloga Junction)	Traffic	6.68852	-1.59605	Very high traffic, very busy junction in the main road from Kumasi to Accra
KU-019	Asokwa (KNUST Main entrance)	Traffic	6.68501	-1.57064	Main entrance for cars to the university campus, roundabout
KU-020	Engineering Guest House	Residential	6.67018	-1.57953	End of a quiet road on university campus, surrounded by a forest

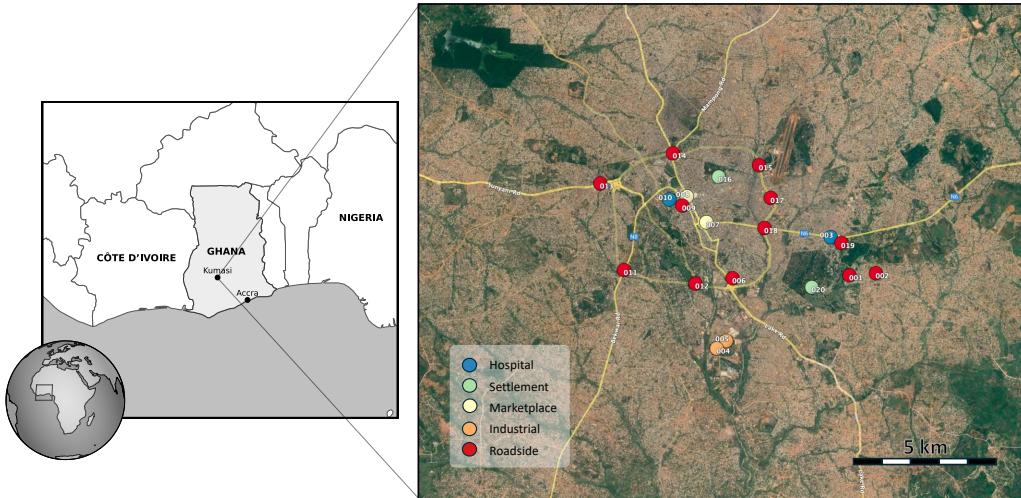

Figure 2: Network locations and their classification within the city of Kumasi, Ghana. Satellite basemap taken from Google Maps ©2025 Google. Map accessed November 2025.

120 **2.3 Creation of a local air quality laboratory**

The objective was to establish the first independent, locally operated air quality (AQ) laboratory in Kumasi, capable of preparing and analysing diffusion tubes without dependence on foreign laboratories. The lab was designed with a focus on simplicity and economy—minimizing the use of costly equipment and consumables and avoiding complex analytical techniques.

125 The methodology for PDT preparation, deployment, and analysis followed the best practices outlined by Targa and Loader (2008), which served as the foundation for the lab's protocols. These guidelines were adapted as needed to suit local conditions (see Sect. 2.3.1 and 2.3.2).

130 The laboratory was developed collaboratively by three teaching assistants from the Chemical Engineering Department at KNUST and three master's students from the Faculty of Industrial Design Engineering at TU Delft, Netherlands. A comprehensive lab manual was created (published as Eckert et al., 2025) detailing all procedures step by step. This manual, along with instructional videos, now forms the core training resource for new local staff.

135 A Hach DR5000 spectrophotometer was donated by the Utrecht University, Netherlands. Tube holders were made from two pieces of wood (around 20 cm long) nailed together in an L-shape, see Fig. 4. The top part has 2 cm diameter holes to accommodate the tubes. The lower part, mounted to the poles, includes two holes for zip ties to secure it to a pole at the measurement site.

2.3.1 Diffusion tube preparation

Before assembling and preparing the diffusion tubes, all components undergo thorough cleaning to minimize the risk of cross-contamination. The cleaning process involves washing the parts with soap and warm water, followed by immersion in

140 a 10% hydrochloric acid (HCl) solution to remove any remaining residues or contaminants. The components are rinsed thoroughly with deionised water to eliminate any traces of the acid or impurities.

Once cleaned and dried, the stainless-steel grids are coated with the sticky TEA solution. This coating can be applied using one of two methods. In the pipetting method, a solution of 20% TEA in deionised water is used, with approximately 50 microlitres of TEA solution applied to each tube. Alternatively, the dipping method involves immersing the grid in a TEA solution mixed with 50% acetone. The grids are thoroughly mixed in the solution and then air-dried on an absorbent surface
145 (paper towel) to allow the coating to adhere properly.

2.3.2 Diffusion tube analysis

After exposure, the batch of collected samples are analysed at the laboratory. The procedure involves three main steps: (1) extraction of nitrite from the coated grids of the exposed tubes using Saltzman/Griess reagents as colorimetric reagents, (2) spectrophotometric analysis of the resulting solution to quantify the mass of nitrite formed, and (3) calculation of the average
150 ambient concentration of NO₂ based on the amount of nitrite detected (absorbance at 542 nm) and the known exposure duration.

First, 3 mL of Griess reagent is added to the grids of each test tube to extract the nitrite and facilitate colour development. The Griess reagent is prepared by mixing equal volumes of two solutions: 0.14 mg L⁻¹ N-(1-naphthyl) ethylenediamine dihydrochloride (NEDA), and 0.02 g L⁻¹ sulphanilamide solution. This solution was prepared by dissolving
155 sulphanilamide in 95% (v/v) deionized water and 5% (v/v) hydrochloric acid (37% concentrated HCl).

Before analysing a new batch of samples, and after preparing fresh reagent, a calibration curve is established to define the relationship between absorbance and nitrite mass. This involves measuring the colour development (colourification) of standard sodium nitrite (NaNO₂) solutions at known concentrations. The absorbance of each standard solution is recorded at 542 nm using a spectrophotometer. The calibration always includes a blank (zero standard) to correct for any offset.

160 Once the calibration curve is constructed, the absorbance values of the extracted diffusion tube samples can be used to determine the amount of nitrite formed during exposure.

2.3.3 Calculation to ambient NO₂ concentration

The average temperature and pressure during exposure is needed in the calculation of the ambient NO₂ concentration from the nitrite mass. The following formula is used:

$$165 \quad C = \frac{m_s - m_b}{\theta t} \frac{T}{T_{ref}} \frac{P_{ref}}{P} \quad (1)$$

Here, C is the average concentration of NO₂ during the measurement (in $\mu\text{g m}^{-3}$), m_s is the mass of nitrite in the sample measured in the laboratory (μg), and m_b is the mass of nitrite measured in a blank sample in the laboratory (μg). The blank sample is taken from the same batch of tubes but has not been exposed to the environment. T is the average temperature at the measurement location in Kelvin. T_{ref} is the reference temperature, here 293 K. P is the average pressure at the

170 measurement locations, and P_{ref} is the reference pressure, here 1013 hPa. t is the exposure time, i.e. the time between opening and closing the sampling tubes (s). θ is the sampling uptake rate (m^3/s), determined by diffusion in the tube:

$$\theta = D \frac{A}{L} \quad (2)$$

175 D is the diffusion coefficient of NO_2 ($\text{m}^2 \text{ s}^{-1}$), A is the cross-sectional area of the tube ($8.1 \times 10^{-5} \text{ m}^2$), and L is the length of the tube ($7.9 \times 10^{-2} \text{ m}$). D is temperature-dependent and is calculated from a reference diffusion coefficient D_{refd} ($1.54 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ at 298 K) using:

$$D = D_{\text{refd}} \left(\frac{T}{T_{\text{refd}}} \right)^n \quad (3)$$

where T is again the average temperature at the measurement location (in K). T_{refd} is the reference temperature (here 298 K), and $n=1.81$ is the empirical best fit for NO_2 in air (Massman, 1998).

180 2.4 Satellite observations

TROPOMI is a nadir-viewing imaging spectrometer aboard the Sentinel-5P satellite (Veefkind et al., 2012). Launched in October 2017, it is orbiting the Earth in a sun-synchronous orbit at an altitude of approximately 800 km. The overpass time is around 13:30 local solar time.

185 The chemical composition of the atmosphere is obtained from hyperspectral measurements of sunlight backscattered by Earth's atmosphere. From the position and depth of the absorption lines the column density of trace gasses like NO_2 can be determined (e.g. van Geffen et al., 2020). The retrieval algorithm converts the so-called slant column density into a total vertical column density and separates the total column density in a stratospheric and a tropospheric part.

The tropospheric column density V_{trop} represents the total number of NO_2 molecules contained within a vertical column with unit area in the troposphere. If $n(l)$ represents the number density at height l , then the true column density is given by

$$190 \quad V_{\text{trop}} = \int_{\text{trop}} n(l) dl \quad (4)$$

In practice, the satellite retrieval algorithm provides an estimate \hat{V}_{trop} of this value. The retrieved column depends on how sensitive the measurement is to concentrations at different altitudes. This vertical sensitivity is described by the averaging kernel $A(l)$, such that

$$\hat{V}_{\text{trop}} = \int_{\text{trop}} A(l) n(l) dl \quad (5)$$

195 The averaging kernel (AK) quantifies how a perturbation in the true (but unknown) atmospheric profile at height l affects the retrieved column (Eskes & Boersma, 2003). A value close to 1 implies high sensitivity to that layer, while values near 0 indicate low sensitivity.

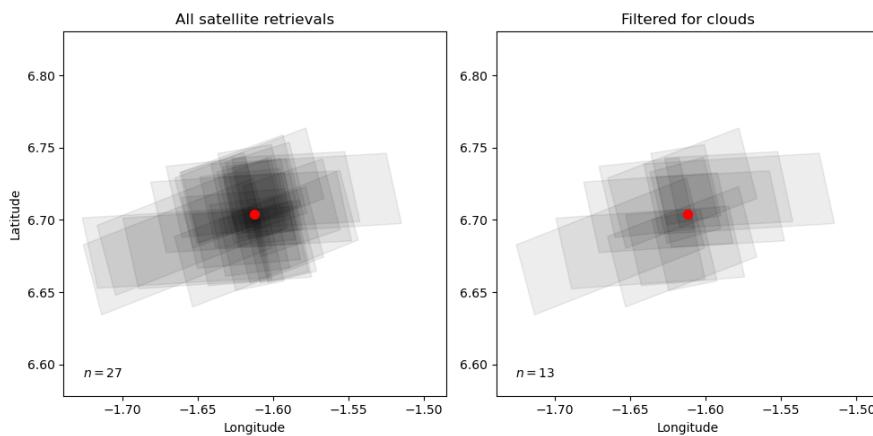

In discrete form, for an atmosphere divided into a finite set of layers, Eq. (5) becomes

$$\hat{V}_{\text{trop}} = \sum_l A_l V_l \quad (6)$$

200 where V_l represents the partial column density in layer l . The elements A_l are calculated using a radiative transfer model that incorporates an *a priori* profile, scattering and absorption by clouds and surface, as well as observation-specific parameters such as the solar zenith angle and the instrument's viewing geometry.

We use the latest level-2 retrieval product for TROPOMI tropospheric NO₂ column densities and their associated AKs, version 2.4 (Eskes et al., 2022; van Geffen et al., 2022), which can be downloaded at the Copernicus Data Space Ecosystem 205 (<https://dataspace.copernicus.eu/>). The averaging kernel calculation of the retrieval is based on *a priori* profiles from the global chemistry model TM5-MP (Williams et al., 2017), run at a 1°×1° spatial resolution.

210 **Figure 3: Sampling of location KU-016 (red dot) by TROPOMI during the measurement campaign (7 March – 3 April). The left panel shows all satellite footprints in this period for a 28 x 28 km² area (n=27); the right panel shows only satellite footprints from valid retrievals under sufficiently cloud-free conditions (n=13).**

Maps of average tropospheric column densities \bar{V} corresponding to the Palmes measurement period are created by stacking all footprints of retrievals marked with a quality value > 0.75, i.e. valid retrievals with cloud radiance fraction below 50%. Each overpass, a given location is sampled by a different satellite footprint, see Fig. 3. As larger footprints are less representative for the area, we take a weighted average of individual retrievals \hat{V}_i covering that location

$$215 \quad \bar{V} = \frac{\sum_i w_i \hat{V}_i}{\sum_i w_i} \quad (7)$$

taking weighting factor $w_i = 1/A_i$, with A_i representing the area of footprint i .

2.5 Kumasi measurement campaign

For the Kumasi measurement campaigns, we used two batches of 50 tubes, prepared and analysed by Buro Blauw Luchtkwaliteit—an ISO 17025-accredited air quality laboratory based in Wageningen, the Netherlands. The tubes (referred 220 to as “remote-lab tubes”) were prepared within two weeks prior to deployment and analysed within four weeks following exposure. In addition, 100 unprepared tubes of the same type and material were brought from Buro Blauw to Ghana. These were prepared and analysed at the newly established laboratory facility at KNUST (referred to as “local-lab tubes”). By

conducting side-by-side measurements, the performance and reliability of the local laboratory could be evaluated (see Sect. 3.2). After use, the local-lab tubes are cleaned and recycled in subsequent measurement cycles.

225 To explore scalable solutions for Palmes networks in Ghana and other countries on the continent, we also tested diffusion tubes made from materials available at local markets. Development and validation of these locally made tubes is ongoing and will be presented in a separate study.

The tube holders were mounted on existing poles using tie wraps, positioned at a height of approximately 2 meters (see Fig. 4). The remote-lab diffusion tubes were deployed across all 20 selected monitoring sites. To assess the precision of the 230 method, duplicate (duplo) measurements were conducted at each location.

In addition, blank tubes were installed at 8 of the sites. These tubes were sealed (i.e., not exposed to ambient air) by keeping their end plugs in place. This allowed for the evaluation of potential degradation of the TEA coating over the course of the measurement period.

235 **Table 2: Meteorological data with mean temperature and pressure during the NO₂ measurement cycles.**

Period	Days	Start	End	Mean temperature (°C)	Mean surface pressure (hPa)
Cycle 1	13	7 March 2025	20 March 2025	28.6	978
Cycle 2	14	20 March 2025	3 April 2025	28.0	978

The measurement campaign consisted of two sampling cycles, each lasting approximately two weeks (see Table 2). At the start of Cycle 1, remote-lab diffusion tubes were placed in tube holders mounted on signposts or lamp posts found at the 20 monitoring sites. Mounting height is approximately 2 meters (see Fig. 4).

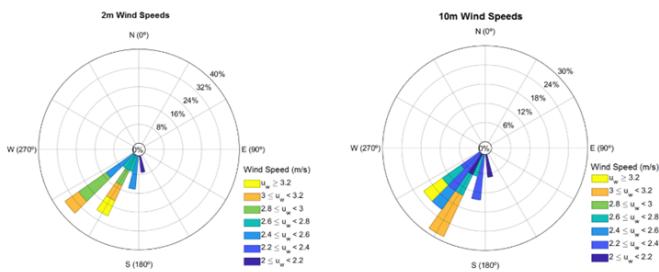

240 At the end of Cycle 1, the tubes were retrieved and replaced with those designated for Cycle 2. For this cycle, additional local-lab tubes were deployed alongside the remote-lab tubes at 10 of the sites to enable side-by-side comparison. All tubes were successfully retrieved at the end of both cycles, with none missing. No insects or spiders were found inside.

245 **Figure 4: Deployed Palmes diffusion tubes mounted on site: one blank sample and two tubes measuring in duplo.**

3. Results of the campaign

Historical hourly meteorological data for Kumasi Airport (287 m above sea level), obtained from Open Meteo's Historical Forecast API (<https://open-meteo.com/en/docs/historical-forecast-api>), indicate that weather conditions were comparable across both sampling cycles. The average temperature during the measurement period was 28.3 °C, with an average surface pressure of 978 hPa (see Table 2). Prevailing winds in March were predominantly south-westerly, as illustrated by the wind roses in Fig. 5. Average wind speeds at 10 m were 6.8 and 6.2 km/h for Cycle 1 and 2, respectively. The total precipitation in Cycle 1 was 35 mm, accumulated in 35 rainy hours. The total precipitation in Cycle 2 was 114 mm, accumulated in 88 rainy hours.

255 **Figure 5: Wind roses for Kumasi Airport for March 2025.**

3.1 Precision and measurement bias

A total of 40 duplo measurements were conducted across the monitoring locations. As shown in Fig. 6, 15 duplos (37.5%) exhibited a difference of less than $1 \mu\text{g m}^{-3}$, while 26 duplicates (65%) showed a difference of less than $2 \mu\text{g m}^{-3}$. Using the variance of the differences in the duplo measurements, we estimate the precision of the method at $3.0 \mu\text{g m}^{-3}$.

260 It should be noted that the exposure period was relatively short—only two weeks. For the more commonly used four-week exposure period, a higher level of precision is expected.

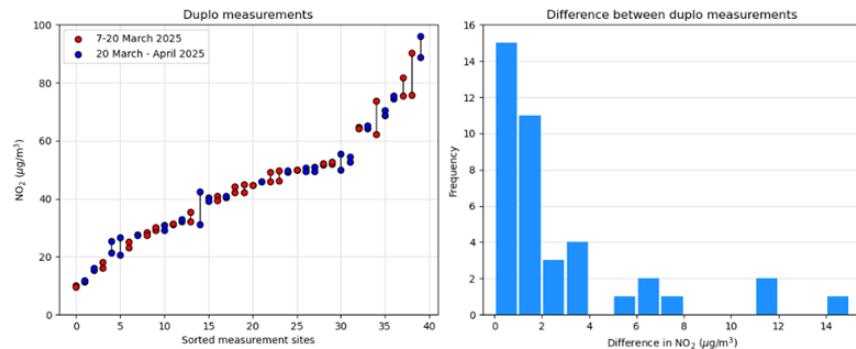

Figure 6: Results of duplo measurements done in the Kumasi network, sorted from small to large NO₂ concentrations (left). Most duplos agree within 2 µg m⁻³ (right).

265 Eight on-site blank measurements were performed, 4 at each sampling cycle. One tube, 070-035, was kept as a lab blank, shielded from sunlight under room temperature conditions. The results are listed in Table 3.

Table 3: NO₂ concentration of Blank measurements

Period	Location ID	Tube ID	Nitrite mass (µg)	NO ₂ conc (µg m ⁻³)
Cycle 1	KU-001	069-001	0.0431	2.56
Cycle 1	KU-004	069-020	0.0407	2.42
Cycle 1	KU-011	069-007	0.0453	2.70
Cycle 1	KU-020	069-009	0.0357	2.21
Cycle 2	KU-001	070-041	0.0489	2.68
Cycle 2	KU-004	070-017	0.0571	3.06
Cycle 2	KU-011	070-020	0.0476	2.54
Cycle 2	KU-020	070-013	0.0306	1.62
Cycle 2	Lab blank	070-035	<0.02	—
Average				2.47

270 The average of the on-site blank samples is 2.47 µg m⁻³ in Cycle 1 and 2.48 µg m⁻³ in Cycle 2. The nitrite mass of the lab blank was found to be below the detection limit of 0.02 µg. The nitrite formation found in the other tubes is therefore assumed to originate from degradation of the TEA once exposed to elevated temperatures and solar radiation at the sampling site. Assuming that a similar degradation effect also occurs in the exposed (non-blank) tubes, we account for this bias by subtracting 2.47 µg m⁻³ in the results.

275 Measurements might be subject to site-specific biases. Differences due to wind effects are expected to be minimal, as all diffusion tubes were mounted using identical holders on free-standing poles, ensuring consistent exposure across sites. However, local variations in temperature—such as those caused by shaded versus sun-exposed locations—could introduce some degree of bias. Quantifying the impact of such micro-environmental factors is beyond the scope of this study.

3.2 Kumasi network measurements in March 2025

280 Table 4 lists the NO₂ concentrations found at the network locations, where the duplo measurements have been averaged and bias-corrected by 2.47 µg m⁻³. Differences between the two measurement periods are minimal. This is consistent with the nearly identical meteorological conditions during both cycles, in terms of temperature, wind speed and wind direction. Notably, the more frequent light rain in Cycle 2 hardly influences the NO₂ concentrations. Averaging the results for each site provides a more robust dataset, considered to be representative of air quality conditions in Kumasi during March 2025.

285

Table 4: Estimated NO₂ concentrations at the network locations after bias correction, sorted from small to large values, for 7–20 March 2025 (Cycle 1) and 20 March – 3 April 2025 (Cycle 2).

Location ID	NO ₂ (Cycle 1) (µg m ⁻³)	NO ₂ (Cycle 2) (µg m ⁻³)	NO ₂ (averaged) (µg m ⁻³)
KU-020	6.5	7.5	7.0

KU-013	78.6	75.0	76.8
KU-014	83.0	92.4	87.7
Average	42.8	42.8	42.8

A wide range of NO₂ concentrations was observed across Kumasi, as illustrated in Fig. 7. The spatial distribution clearly indicates that NO₂ levels are predominantly influenced by road traffic.

The lowest NO₂ concentration—7 $\mu\text{g m}^{-3}$ —was recorded at KU-020 (Engineering Guest House), located within the green and relatively traffic-free KNUST campus. In contrast, the highest concentrations were found at traffic-dense locations, including KU-018 (Anloga Junction, 69 $\mu\text{g m}^{-3}$), KU-013 (Sofoline Interchange, 77 $\mu\text{g m}^{-3}$), and KU-014 (Suame Circle, 88 $\mu\text{g m}^{-3}$).

295 Measurements taken at industrial sites (KU-004 and KU-005) did not show outstanding concentrations, suggesting that industrial emissions contribute less significantly to ambient NO₂ levels in these areas.

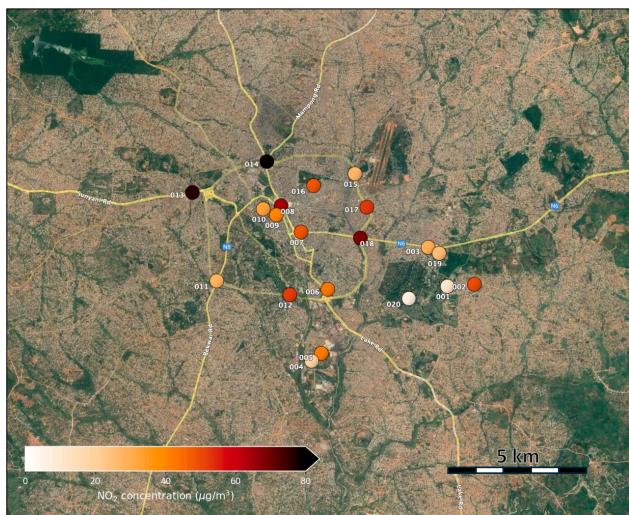

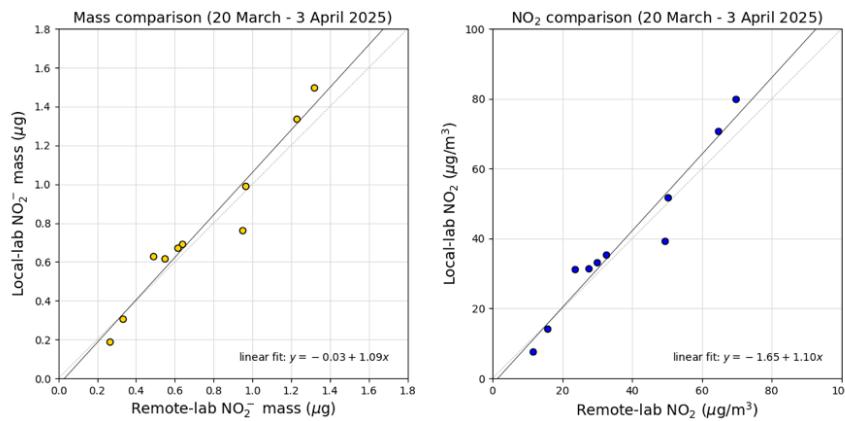

Figure 7: NO₂ concentrations measured in Kumasi by PDTs in March 2025. (Basemap taken from Google Maps ©2025 Google.)

3.3 Validation of locally prepared and analysed tubes

300 During Cycle 1, the air quality laboratory facility at KNUST was established and became operational. For Cycle 2, 10 locally prepared tubes were deployed alongside remote-lab tubes at 10 sites within the measurement network. The local-lab tubes were analysed shortly after their collection at the end of Cycle 2. Since they are made from the same materials and have identical dimensions as the remote-lab tubes, they are assumed to experience similar degradation and were therefore corrected by subtracting $2.47 \mu\text{g m}^{-3}$.

305 The scatter plots in Fig. 8 show data pairs closely aligned with the 1:1 line, indicating strong agreement between the two sets of measurements. The relatively low scatter demonstrates that the KNUST laboratory can reliably reproduce results comparable to those of the accredited laboratory.

310 **Figure 8: Comparison of results between tubes prepared and analysed at the local KNUST lab and tubes prepared and analysed at the remote accredited lab. (left) The mass determination, and (right) the conversion to ambient NO₂ concentration.**

The measured values for each data pair are presented in Table 5. Note that the remote laboratory results are generally lower than those from the local laboratory, possibly due to sample degradation during the 27-day delay before analysis, compared with 2 days for the local lab.

315

Table 5: Comparison between local and remote lab results

Location ID	NO ₂ remote-lab (µg m ⁻³)	NO ₂ local-lab (µg m ⁻³)	NO ₂ difference (µg m ⁻³)
KU-001	15.6	14.3	-1.3
KU-002	50.2	51.8	1.6
KU-003	27.6	31.4	3.8
KU-004	23.7	31.2	7.6
KU-007	49.4	39.3	-10.2
KU-008	64.7	70.7	6.0
KU-010	32.5	35.4	2.8
KU-015	30.0	33.2	3.2
KU-018	69.6	79.9	10.3
KU-020	11.6	7.5	-4.1
Average	37.5	39.5	2.0

To estimate the uncertainty in NO_2 concentrations determined by the local laboratory, we calculate the variance of the differences D_i between paired measurements. This allows us to approximate the error associated with the PDT results from the local lab, σ_{local} , using the following relation:

320
$$\sigma_{\text{local}}^2 + \sigma_{\text{remote}}^2 = \frac{1}{n-1} \sum_{i=1}^n (D_i - \bar{D})^2 \quad (8)$$

where \bar{D} is the mean of the differences, here $2.0 \mu\text{g m}^{-3}$, and σ_{remote} represents the estimated uncertainty of duplicate measurements analysed at the accredited (remote) laboratory, estimated in Sect. 3.1 to be $3.0 \mu\text{g m}^{-3}$. Based on this approach, the resulting uncertainty in NO_2 concentration for the local laboratory is estimated at $5.1 \mu\text{g m}^{-3}$.

It should be noted that this estimate is not very robust due to the small sample size ($n = 10$) and the relatively short exposure 325 period of two weeks. Longer exposures—such as the more common four-week period—are expected to yield more accurate and reliable nitrite mass determinations.

4 Comparison with satellite retrievals

Satellite observations of tropospheric NO_2 obtained from TROPOMI and averaged over the Kumasi region for the period 7 March–3 April 2025 are presented in Fig. 9. Clearly visible is the build-up of NO_2 column densities downwind (northeast) 330 under the prevailing south-westerly winds. Also visible are the pockets of cleaner air in the unbuilt areas between the suburbs west and south of Kumasi.

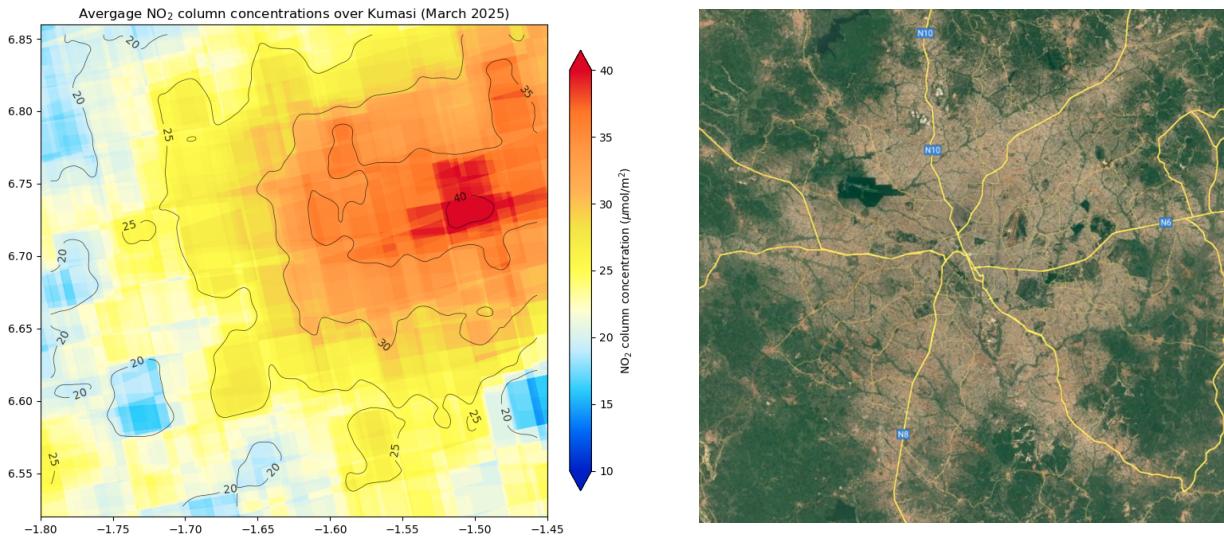

Figure 9: Averaged satellite measurement of tropospheric NO_2 columns density over Kumasi from 7 March to 3 April 2025. The map represents an area of $38 \times 38 \text{ km}^2$. Contour lines are shown for the measurement field smoothed with a Gaussian kernel of $\sigma=400 \text{ m}$. (Basemap taken from Google Maps ©2025 Google.)

4.1 Column-to-surface ratio

Comparison of Fig. 7 and 9 shows no clear spatial relation between the satellite column measurements and the surface concentrations. Elevated NO₂ levels in upwind regions are not readily apparent in surface measurements, although they might be detectable with a more extend ground-based monitoring network that includes more urban background stations.

340 The main reason for the poor spatial relation is the scale mismatch: TROPOMI's footprint (5.5 × 3.5 km² at best) averages the sharp local gradients found near strong emission sources such as traffic arteries. The relationship is further complicated by the unknown vertical distribution of NO₂, as tropospheric columns integrate contributions from air masses of different origins, ages, and mixing states. Additional atmospheric modelling would therefore be needed to resolve fine-scale structures in surface air pollution from satellite observations (see, e.g., Mijling et al., 2025).

345 Other limitations for direct comparison include the once-daily overpass of TROPOMI, which captures NO₂ concentrations around 13:30 local solar time, which might not be representative for daily averages. Furthermore, since the satellite retrievals rely on sufficiently cloud-free conditions, the lack of data under cloudy conditions can introduce a sampling bias in monthly averages (see e.g. Glissenaar et al., 2025).

Nevertheless, it is interesting to look at the ratio between average tropospheric column densities and average ground 350 concentrations on an urban scale, as TROPOMI retrievals of tropospheric columns have been shown to correlate strongly with in-situ surface measurements, particularly in urban environments (Cersosimo et al., 2020; Goldberg et al., 2021; Ialongo et al., 2020; Jeong et al., 2021). Understanding this relationship provides a basis to monitor surface concentrations using satellite measurements alone. Table 6 compares the column-to-surface ratio for Kumasi with those of European cities of similar size for March 2025.

355

Table 6: Comparison between average tropospheric column densities from TROPOMI and surface concentrations for different cities in March 2025, sorted from high to low column.

(b) Within 10 km radius; between parenthesis the number of reference stations classified as traffic station
360 (c) Area averaged tropospheric column density, radius 10 km around city centre
(d) Lowest tropospheric column concentration found in a radius of 15 km around city centre
(e) Average for March 2020 from Ogawa passive samplers (Wang et al., 2022)

Surface NO₂ concentrations were extracted from the European Environment Agency (EEA) database (EEA, 2025) for March 365 2025. Urban averages are calculated from all regulatory monitoring stations located within 10 km of each city centre, having at least 80% completeness in its hourly measurements. To put our Kumasi measurements further in perspective, we included the average surface concentration for Accra in March 2020, measured by Ogawa passive samplers (Arku, 2021) from the study by Wang et al. (2022).

Average tropospheric column concentrations were obtained from maps of stacked tropospheric NO₂ columns (as described in 370 Eq. 7), calculated within a 10 km radius of each city centre. The background column concentration is defined as the minimum value within a 15 km radius.

Table 6 shows that the column-to-surface ratios in Kumasi and Accra are significantly lower than those in the European cities. As illustrated in Fig. 10, this is a notable finding: small columns observed by TROPOMI over West Africa do not necessarily correspond to low surface concentrations—contrary to what one might intuitively conclude from NO₂ maps when 375 presuming a fixed column-to-surface ratio.

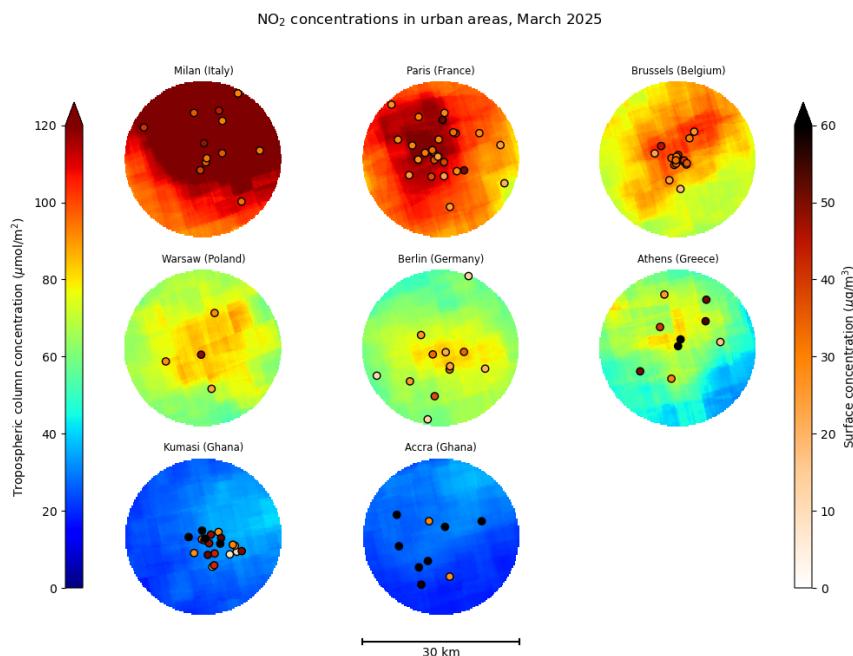

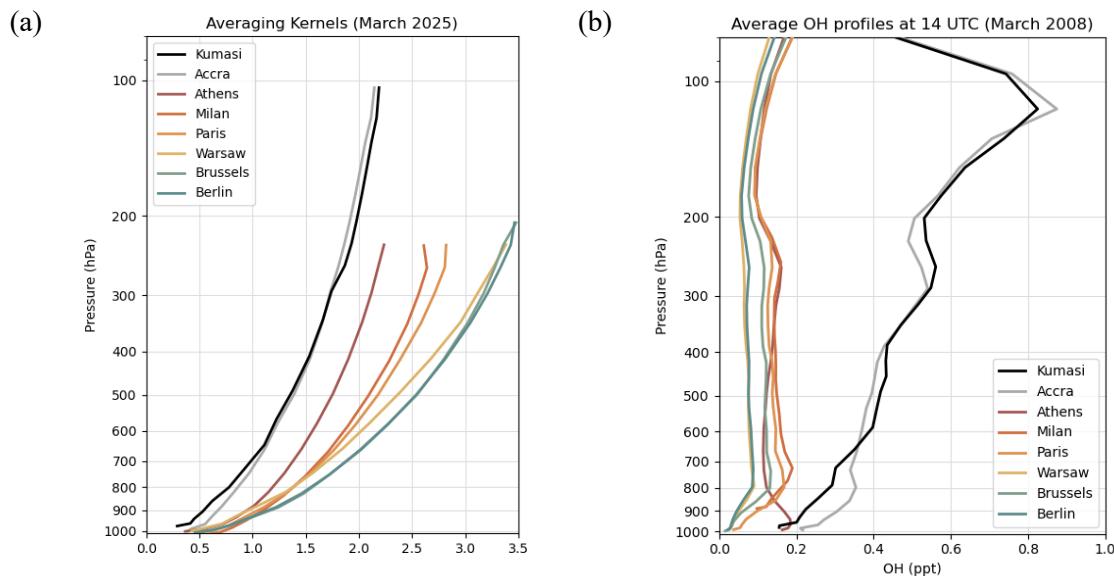

Figure 10: Comparison between averaged NO₂ tropospheric column retrievals by TROPOMI and surface concentration measurements for selected cities in March 2025. (Note that the Accra surface data is for March 2020.)

4.2 Averaging kernels and NOx lifetime

380 The low columns over Ghanaian cities can be partly explained by the reduced sensitivity of the retrieval method near the surface in combination with coarse *a priori* NO₂ profiles from TM5-MP. Averaging kernels over Accra and Kumasi (Fig. 11a) confirm a reduced sensitivity throughout the troposphere. This reduction is closely associated with the high aerosol loading in the region, as reflected by elevated aerosol optical depth (AOD) values.

385 Table 7 presents the mean TROPOMI AOD at 494 nm (KNMI, 2025) in March 2025 for a 30 × 30 km² area centred on each city. Values well above 1 suggest the presence of substantial haze, resulting primarily from long-range dust transport from the Sahara and Sahel regions, as well as smoke from biomass burning, which remains active during March. The resulting decrease in atmospheric transparency effectively obscures near-surface urban pollution from satellite detection, thereby contributing to the decrease in vertical sensitivity towards the surface.

390 **Figure 11: (a) Tropospheric averaging kernels from TROPOMI over selected cities, averaged over March 2025. (b) Average OH profiles around satellite overpass time from TM5-MP simulations at 1°x1° resolution for March 2008.**

Another reason for the relatively low tropospheric column densities over Kumasi can be found in the NOx chemistry. During the day chemical loss of NOx is dominated by the oxidation of NO₂ by the hydroxyl radical (OH):

395 The associated lifetime of NO₂ is

$$\tau = 1/k[\text{OH}], \quad (9)$$

where k is the reaction rate and [OH] the hydroxyl concentration, expressed in molecules m⁻³. The primary daytime source of OH is the photolysis of ozone (O₃) followed by a reaction with water vapor:

Compared to mid-latitudes, OH production is enhanced in the tropical lower troposphere due to stronger solar radiation, more abundance of water vapor, and higher temperatures. This is confirmed by simulations of the global chemistry model TM5-MP for March 2008, conducted around the satellite overpass time at a $1^\circ \times 1^\circ$ spatial resolution (Fig. 11b). Average OH concentrations between 1000 and 850 hPa are shown in Table 7. The corresponding lifetime τ is estimated using Eq. 9, 405 assuming a typical rate constant $k=1.1 \text{ } 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Sander et al., 2006). In the lower troposphere, k is only weakly dependent on temperature within the 250–300 K range. It should also be noted that these lifetimes represent averages over a relatively large $1^\circ \times 1^\circ$ grid cell, whereas lifetimes within urban areas can be considerably shorter (Beirle et al., 2011; Lorente et al., 2019).

From the table can be seen that lifetimes found in Kumasi are 1.1–4.9 times shorter than found in European cities. This 410 means that while NO_2 concentrations found at the surface close to emissions sources can be high, NO_2 column densities will be lower, as the tropospheric column contains air parcels of different origins, with more aged chemistry.

Table 7: Differences in Aerosol Optical Depth (March 2025) and NO_2 lifetime due to loss against OH (March 2008)

City	AOD @ 494 nm	[OH] ^(a) (ppt)	[OH] ^(a) ($10^6 \text{ molecules cm}^{-3}$)	Lifetime (h)

4.2 NO_2 height-distribution model

To better quantify the differences in column-to-surface NO_2 ratios between European and Ghanaian cities, information on the vertical distribution of NO_2 is required. Although this distribution is not directly known without dedicated atmospheric modelling, we can approximate it by introducing a simplified height-distribution model (Fig. 12) and fitting it to surface 420 measurements and tropospheric column densities, explicitly incorporating their averaging kernels in the retrieval.

The model assumes that background NO_2 is well-mixed within the planetary boundary layer (PBL) of height h_{PBL} at the time of the satellite overpass, consistent with NO_2 sonde observations (Sluis et al., 2010). Contributions from free-tropospheric NO_2 to the tropospheric column density are considered negligible.

The urban NO_2 component, originating from local emissions, is assumed not to be fully mixed vertically. Observations from the Eiffel Tower, for example, show that NO_2 concentrations at 300 m height in central Paris are about 45% lower than surface levels around the satellite overpass time (Dieudonné et al., 2013, Fig. 1b). Accordingly, we represent the urban plume as being well-mixed within an effective layer of height h_{mix} , located below the PBL.

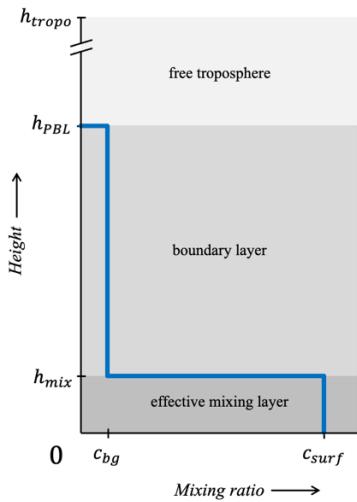

Figure 12: Vertical distribution model for urban NO_2 (blue line) with two fit parameters: the background is assumed to be well-mixed throughout the boundary layer with mixing ratio c_{bg} , while the urban contribution is only well-mixed up to an effective height h_{mix} . There is no NO_2 in the free troposphere.

First, we determine the background surface concentration c_{bg} . We estimate the background column density \hat{V}_{bg} from the lowest TROPOMI retrieval value found within a 15-km radius around the city centre (see Fig. 10), and take h_{PBL} taken from the ERA5 reanalysis (Hersbach et al., 2023). For a given concentration c_{bg} (in ppb), the partial background column in an atmospheric layer l is

$$V_{\text{bg},l} = c_{\text{bg}} \times 10^{-9} \frac{N_A}{M_{\text{air}}g} \Delta P_l^{\text{PBL}}, \quad (10)$$

where N_A is Avogadro's number, M_{air} the molar mass of dry air, and g the gravitational acceleration. The term ΔP_l^{PBL} is the pressure thickness of the layer within the PBL: for the layer containing h_{PBL} , only the portion below the PBL top is used, and for layers entirely above the PBL, $\Delta P_l^{\text{PBL}} = 0$. Using Eq.6, we find the relation between c_{bg} , the observed \hat{V}_{bg} , and the AK elements A_l , which allows us to solve for c_{bg} .

In the second step, we determine the mixing layer height h_{mix} . We estimate the urban column density \hat{V} from the mean TROPOMI retrieval within a 10-km radius of the city centre, and take the surface concentration c_{surf} from the in-situ measurements. For the block profile (blue curve in Fig. 12), the partial column in layer l is

$$V_l = V_{\text{bg},l} + (c_{\text{surf}} - c_{\text{bg}}) \times 10^{-9} \frac{N_A}{M_{\text{air}g}} \Delta P_l^{\text{mix}}, \quad (11)$$

445 where ΔP_l^{mix} is the pressure thickness up to the mixing-layer height h_{mix} , and zero above it. Using Eq. 6, we determine the value of h_{mix} for which the profile matches the observed \hat{V} , given the averaging kernel A_l .

Note that surface concentrations must correspond to the satellite overpass time. For the European cities, hourly measurements at 13:00 UTC are used; these are lower than the daily mean values by factors ranging from 0.63 (Warsaw, Berlin) to 0.76 (Milan, Paris). For Kumasi and Accra, we apply a factor of 0.69 is applied to estimate values at overpass time 450 from mean surface concentrations.

Table 8 presents the fit results and the recalculated column densities, derived by vertically integrating the profiles without applying the averaging kernel (Eq. 4). Comparing with the results from Table 6, the recalculated tropospheric column densities for Paris, Milan, Brussels, Berlin in March 2025 increase by 30-40%. This is consistent with Douros et al. (2023), who attribute the underestimation of retrievals over emission hot spots to the coarse ($1^\circ \times 1^\circ$) TM5-MP profiles taken as *a priori*. 455

In contrast, the recalculated tropospheric NO₂ column over Kumasi increases by a factor of 2.5. This larger correction can be attributed to a combined effect of the coarse *a priori* profile and a possible underestimation of the urban emissions in TM5-MP, and the reduced retrieval sensitivity caused by the high aerosol loading.

Despite this increase, the recalculated NO₂ columns over Kumasi ($76 \mu\text{mol m}^{-2}$) and Accra ($54 \mu\text{mol m}^{-2}$) remain 460 substantially smaller than those observed over the European cities ($132 \mu\text{mol m}^{-2}$ on average). The lower vertical mixing height h_{mix} suggest that the shorter chemical lifetime—discussed in the previous section—is likely a contributing factor.

The resulting lower effective mixing height might seem counterintuitive, as one would expect stronger convection due to higher surface temperatures. Note that the very low value over Accra may partly result from an overestimation of the surface concentration (March 2020 may not represent March 2025) or from the reduced air mass residence time over the city due to 465 stronger winds.

Table 8: Recalculated tropospheric NO₂ column densities obtained by fitting the vertical distribution model to combined column and surface observations

5. Discussion and conclusion

We established the first-ever Palmes diffusion tube measurement network in Kumasi, comprising 20 monitoring sites selected to reflect a diverse mix of urban environments, including traffic intersections, industrial zones, markets, hospitals, and residential areas. Tubes are replaced every month.

475 Blank samples revealed that PDTs are subject to degradation of triethanolamine (TEA) when exposed to ambient conditions. To account for this, a correction of $2.47 \mu\text{g m}^{-3}$ was uniformly applied to all measurements. From the duplo samples, we estimate the measurement uncertainty of the method to be $3 \mu\text{g m}^{-3}$. It should be noted that the exposure duration in this 480 campaign was relatively short (2 weeks), which may lead to reduced accuracy; a 4-week exposure period is more typical and would likely yield more precise results.

A wide range of ambient NO_2 concentrations was recorded across Kumasi during March 2025, ranging from $7 \mu\text{g m}^{-3}$ in low-traffic, green areas (e.g., the KNUST campus) to $88 \mu\text{g m}^{-3}$ at major traffic intersections (e.g., Suame Circle). According to 485 the World Health Organization (2021), the recommended air quality guidelines for NO_2 are $25 \mu\text{g m}^{-3}$ for a 24-hour mean and $10 \mu\text{g m}^{-3}$ for an annual mean. Assuming that March is reasonably representative of annual conditions, nearly all monitored sites in Kumasi exceed both WHO thresholds, highlighting a significant public health concern.

490 As observed in many African cities, economic activity in Kumasi is highly concentrated along major roads and highways, more so than in many cities in the Global North. The informal roadside economy is a defining urban feature, with markets, kiosks, street vendors, and transport hubs densely clustered along traffic corridors. As a result, large numbers of pedestrians and roadside workers are exposed to traffic-related air pollution on a daily basis.

Elevated NO_2 levels were also detected near hospitals, raising further concern given the vulnerability of patients recovering 495 from illness. The recorded concentrations at these healthcare facilities substantially exceeded WHO guidelines, underscoring the urgency of addressing transport-related air quality issues in densely populated and sensitive areas.

The citywide average NO_2 concentration in Kumasi was $43 \mu\text{g m}^{-3}$, which is lower than values reported for Accra by Wang 495 et al. (2022). Their 2019–2020 campaign using Ogawa passive samplers recorded an annual average of $68 \mu\text{g m}^{-3}$ (ranging from 28 to $98 \mu\text{g m}^{-3}$ between sites), with a seasonal variation of $60 \mu\text{g m}^{-3}$ during the wet season and $87 \mu\text{g m}^{-3}$ in the dry season. It remains unclear whether the observed difference between Kumasi and Accra reflects differences in site selection, emissions intensity, meteorological conditions, or urban structure.

Side-by-side comparisons show that PDTs prepared and analysed at the newly established KNUST laboratory yield results 500 that closely match those from an accredited reference laboratory. A slight systematic overestimation of $2 \mu\text{g m}^{-3}$ was observed, which may be reduced in future analyses through stricter adherence to laboratory protocols. The measurement uncertainty of the KNUST-processed PDTs is estimated at $5.1 \mu\text{g m}^{-3}$, though this estimate is based on a small sample size and should be interpreted with caution.

The KNUST facility marks a significant advancement in regional air quality monitoring by enabling the local preparation, 505 deployment, and analysis of NO_2 diffusion tubes. This capability supports sustainable, affordable, and scalable monitoring efforts across Ghana and beyond. Beyond the technical achievement, this initiative contributes to the long-term development of local expertise, empowering institutions to independently assess spatial and temporal trends in NO_2 concentrations, identify pollution hotspots (such as congested roads and industrial zones), and evaluate compliance with international air quality standards.

510 Ongoing monitoring is needed to assess seasonal variability, including the effects of wet and dry season meteorology and biomass burning, as background levels observed in March likely differ during the December–February burning season.

Satellite measurements over Kumasi in March reveal the presence of a downwind NO_2 plume driven by dominant south-westerly winds. This plume is not clearly resolved by the existing Kumasi ground monitoring network. Expanding the 515 network to include more urban background stations is necessary to accurately assess the impact of this urban plume on surface concentrations.

Column-to-surface ratios in Kumasi and Accra are significantly lower than those typically observed in European cities. This can only partly be attributed to shorter NO_x lifetimes driven by higher OH abundances. The higher aerosol loading over Ghana reduces retrieval sensitivity in the lower troposphere, increasing the reliance on *a priori* profiles that are both spatially coarse and likely based on underestimated emissions in TM5-MP.

520 To address this, we introduced a simplified height distribution model that links tropospheric column observations to in-situ measurements. The resulting profiles indicate that columns in Kumasi are underestimated by a factor of 2.5 in March 2025, and that the vertical mixing layer over tropical cities is substantially shallower than in mid-latitude urban environments.

The underestimation of tropospheric NO_2 columns leads to a distorted picture of surface concentrations when relying solely 525 on satellite retrievals, potentially missing high surface pollution levels. Improving the application of satellite measurements in low-latitude urban areas therefore requires a more robust understanding of column-to-surface ratios. Long-term vertical profiling (e.g., by drones or sondes) would enable a more accurate characterisation of the urban pollution dome. Our findings

also show the essential role of in-situ networks, such as the one established in Kumasi, for interpreting satellite retrievals and improving our understanding of regional air quality dynamics.

Author contributions

530 BM and BA initiated the project. BA, EY, PA, PD, THE, MM, AGP designed and built the Kumasi laboratory and performed the field measurements. PJA provided the meteorological description. BM performed the data analysis and wrote the manuscript. BM and KFB developed the interpretation of the satellite retrievals. All authors discussed the results and improved the paper.

Competing interests

535 KFB is member of the editorial board of AMT.
