**Abstract.** Contrary to the Antarctic, where ozone recovery has been observed for about a decade, the detection of positive ozone trends in the Arctic remains challenging due to higher natural variability of ozone in that region.

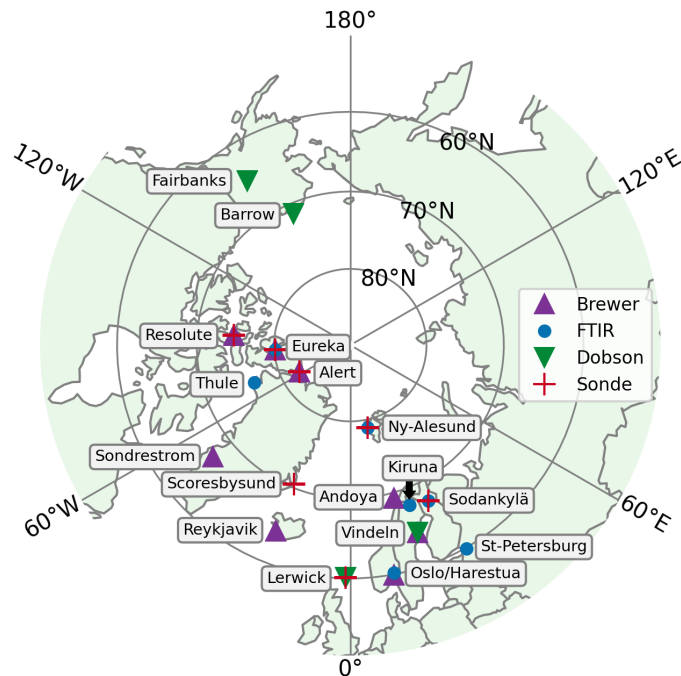

Using a merging of long-term ozone data from Fourier transform infrared spectrometers, ozonesondes, and Dobson and Brewer spectrophotometers, we present regional long-term trends (2000 – 2024) for total, stratospheric and tropospheric ozone. First, ground-based measurements are cross-compared to two satellite data sets (MEGRIDOP and IASI-CDR). This enables the detection of [drifted drifts in](#) ground-based data sets we further exclude from our study. We then use a representativeness study based on CAMS re-analysis data to define regions for which representative trends with reduced uncertainties are obtained by combining data sets from different instruments and stations. Annual and seasonal trends are calculated using a multiple linear

regression technique involving a set of proxies that represent physical processes influencing the natural ozone variability.

10 Annual trends indicate increasing total ozone over the Arctic, and are statistically significant over Canada and Reykjavik (+2.1%/decade) and North-West Europe (Harestua and Lerwick, +0.7%/decade). Ozone recovery is also observed over Canada in the mid-stratosphere (+2.0%/decade) and over the North Pole region (Canada and Ny-Ålesund) in the upper stratosphere (+2.1 to +3.8%/decade). By analysing the sensitivity of the ozone trends to the proxies, we observe a slow down of the expected ozone recovery, especially in the lower stratosphere, due to stratospheric cooling (-0.6%/decade) and to the increase of volume  
15 of polar stratospheric clouds (-0.8%/decade).

## 1 Introduction

Following the discovery of the Antarctic ozone hole (Farman et al., 1985) in the 1980s, the Montreal Protocol of 1987 (and its amendments) banned the production of chlorine-releasing chemicals such as chlorofluorocarbons that were found largely responsible for the global ozone depletion, earning them the name of ozone-depleting substances (ODS). Consequently, a progressive recovery of the ozone layer has been expected since the 2000s, with a projected complete recovery of stratospheric ozone around the 2050s globally (World Meteorological Organization, 2023). While this recovery has been successfully detected above the Antarctic and in the mid-latitudes (at least for the total column of ozone near-global average 60°S – 60°N), it remained elusive above the Arctic until recently (Weber et al., 2022; World Meteorological Organization, 2023). First signs of recovery over the Arctic have been observed for the total column of ozone using ground-based and satellite measurements  
25 (Pazmiño et al., 2023; Bernet et al., 2023; Anjali and Kuttippurath, 2025), and in the upper stratosphere using satellite measurements (Arosio et al., 2019; Sofieva et al., 2021; Anjali and Kuttippurath, 2025). But the largest concentration of ozone in the atmosphere is located in the lower and middle stratosphere, at about 20 km of altitude. There, no recovery has yet been observed and instead, negative trends over the last two decades have been reported in the northern hemisphere (Ball et al., 2018; Nilsen et al., 2024). Model simulations point toward an explanation of these negative trends due to the internal variability of ozone transport for northern mid-latitudes (Chipperfield et al., 2018; Benito-Barca et al., 2025) ~~and to the~~, while in the Arctic, simulations suggest that stratospheric cooling induced by climate change ~~in the Arctic implies large winter and spring losses of stratospheric ozone~~ (von der Gathen et al., 2021). As above the Antarctic, the ozone layer above the Arctic is more strongly impacted by depletion than mid-latitudes due to colder temperatures and the presence of polar stratospheric clouds. At springtime, when coldest temperatures ally with the first sunlight after the polar night, heterogeneous ozone-depleting reactions  
35 primarily occur on the surface of these clouds in the lower stratosphere. The stratospheric cooling thus aggravates the depletion in the lower stratosphere. Moreover, compared to the Antarctic, the detection of positive long-term ozone trends in the Arctic is much more difficult due to a larger natural variability of ozone (Brasseur and Solomon, 2005; Langematz and Tully, 2018) resulting from stratospheric dynamical activity, exemplified by the instability of the Arctic polar vortex (Jonassen et al., 2020). At the same time, expected trends of ozone in the Arctic are very small, about a few %/decade, complicating their detection  
40 over a noisy background.

**Figure 1.** Location of the 17 ground-based stations in the Arctic within 60 – 90°N considered in this study.

~~Parallelly to the stratospheric ozone~~ In parallel to stratospheric ozone trends, we also report on tropospheric ozone trends in the Arctic. Tropospheric ozone is a harmful pollutant with marked health impacts, important to monitor ~~on its own in its own right~~. But it is also necessary to study its impact on the total ozone column budget and separate it from stratospheric ozone trends. In Van Malderen et al. (2025a, b), significant negative tropospheric ozone trends were found in the Arctic for the 2000 – 2022 period in the range of  $-1$  to  $-2$ ppb/decade, while a strong seasonal cycle was highlighted in the tropospheric ozone trends in Law et al. (2023), with a decrease in Spring and increase in Summer over the 1993 – 2019 period.

In this study, we use data from 17 different stations, all located between 60 and 90°N (see Figure 1) and from four different ground-based instrument techniques: Fourier transform infrared (FTIR) interferometers, ozonesondes, Brewer and Dobson spectrophotometers. Simultaneous use of these techniques enables to cover the whole stratosphere and troposphere: FTIR, Brewer and Dobson provide total columns of ozone, ozonesondes yield high-resolution profiles up to about 30 km, and four partial columns (one in the troposphere and three in the stratosphere) can additionally be extracted from FTIR. Each individual technique has been used in the past for trends detection (see e.g. Vigouroux et al. (2008, 2015) for FTIR, Kivi et al. (2007); Christiansen et al. (2017) for ozonesondes and Harris et al. (1997); Fioletov et al. (2023) for Brewer and Dobson).

The detection of stratospheric ozone trends typically requires the use of a ~~multiple-linear~~ multiple linear regression (MLR) in order to account for its ~~large~~ variability, by explaining the time series variance by fitting several influencing physical processes. ~~The Long-term Ozone Trends and Uncertainties in the Stratosphere (LOTUS) initiative (Petropavlovskikh et al., 2019), debuted in 2016, recommends the use of the~~ Those processes are typically the 11-year solar cycle, the Quasi-Biennial Oscillation

(QBO) ~~principal components~~ and the El-Niño Southern Oscillation (ENSO) as ~~explanatory variables (or proxies)~~. In addition, ~~dynamical proxies (such as the~~ in the Long term Ozone Trends and Uncertainties (LOTUS) initiative Petropavlovskikh et al. (2019) . In the Arctic, the large ozone inter-annual variability is driven both by chemistry and by dynamics. Chemistry impacts ozone variability in polar regions through heterogeneous chemistry on polar stratospheric clouds (PSC). Dynamical variability is led by tropospheric planetary waves, which impact the stratospheric temperature and the Brewer-Dobson ~~Circulation, the Arctic Oscillation, etc.)~~ have been used to obtain trends for various measurement techniques (Vigouroux et al., 2015; Coldewey-Egbers et al., 2022) ~~circulation (BDC) (Chipperfield and Santee, 2022), as well as by Arctic Oscillation (AO) which impacts the polar vortex (Lawrence et al., 2020)) or by the equivalent latitude (EL) (Wohltmann et al., 2005). On a local scale, variability also depends on the tropopause pressure (TP) variations through stratosphere-troposphere exchanges. These processes are not independent, as e.g. the PSC formation is linked to the stratospheric temperature, and hence to the strength of the vortex. Various past studies used some of those drivers of polar ozone variability in multiple-linear regression (MLR) models (Vigouroux et al., 2015; Coldewey-Egbers et al., 2022). A systematic statistical analysis of ozone proxies was carried out in Mäder et al. (2007) on ground-based data sets for the 1960 – 2000 period using a stepwise regression procedure. It concluded that in the North polar region, the optimized model includes the EL, PSC, Stratospheric temperature and aerosols. We do not consider aerosols here since in our period of focus there has been no major volcanic eruption in the North Hemisphere. To avoid biases due to preselection of proxies, in this work we also carry a stepwise regression procedure based on all proxies influencing ozone variability (11-year solar cycle, QBO, ENSO, PSC, EL, TP, Stratospheric temperature, BDC, and AO). The stepwise regression automatically selects the most significant proxies in the MLR and avoids overfitting. Overfitting is further controlled by verifying that the fitting is improved while the uncertainties of trends are reduced when adding new proxies. Some of these proxies have their own trend. Depending on the aim, one can choose to de-trend the proxies (as in e.g. Li et al. (2023)), obtaining then an ozone linear trend that contains both influence of ODS and dynamics changes. We prefer here not to de-trend them, in order to obtain the ozone trend that would be due only to ODS changes, following e.g. Weber et al. (2022). Our trends can therefore be directly associated to the "recovery" of stratospheric ozone.~~

~~In this work, trends are calculated with such a MLR together with a stepwise procedure that avoids overfitting. We further reduce the uncertainties of our trends by automatically selecting only the most relevant proxies. We further reduce our trends uncertainties by first~~ combining ground-based measurements into specific geographic regions, defined by performing a representativeness study (Weatherhead et al., 2017) based on the CAMS Re-Analysis data (Inness et al., 2019) for the total column of ozone and all four atmospheric layers, as done for tropospheric ozone in Van Malderen et al. (2025b). We thus obtain regional trends representative of these specific regions. We focus on the 2000 – 2024 period. The merging allows to include shorter time-period measurements or with gaps.

All data sets used in this study are explicitly described in section 2. In section 3, we cross-compare ground-based data sets against two satellite ozone data sets, IASI-CDR (IASI, 2025) and MEGRIDOP (Sofieva et al., 2021). This enables us to validate the quality of our individual ground-based data sets before calculating trends ~~and to also evaluate, while also evaluating~~ the drifts of satellite data sets with respect to ground-based instruments in the Arctic. The representativeness study and resulting regions for all total and partial columns are described in section 4. Finally, we present in section 5 our stepwise MLR model

and the trends obtained in each of these regions for the four atmospheric layers (from 0 to 48 km) and for the total column of ozone.

## 95 2 Ground-based data sets

All ground-based data sets, their instrument's location, repository and time period are summarized in Table 2. The rest of this section describes all these data sets with more details, including a brief discussion of the measurement techniques and of the associated uncertainties.

### 2.1 FTIR interferometers

100 The FTIR interferometers record interferograms from sunlight that are Fourier-transformed into solar absorption spectra. Trace gas abundances, such as ozone abundances, are retrieved from these spectra by using line-by-line spectral fitting softwares (SFIT4 (Hannigan et al., 2024) or PROFFIT (Hase et al., 2004)), including radiative transfer models. Forward model inputs include spectroscopic parameters, climatological a priori information on trace gases concentrations, and 6-hourly pressure and temperature profile information from NCEP. The pressure and temperature-dependences of the ozone line-shapes enable  
105 us to retrieve low-vertical resolution profiles, with four to five distinct degrees of freedom for signal (DOFS), spanning the troposphere and stratosphere from about 0 – 48 km (Vigouroux et al., 2015).

In this study, we use FTIR ozone data sets from the Network for the Detection of Atmospheric Composition Change (NDACC) (<https://ndacc.larc.nasa.gov/>). This network gathers the data sets of 160 ground-based instruments monitoring various components of the atmosphere from 73 active sites around the globe ~~-It represents a massive collaborative effort lasting~~  
110 ~~for about 35 years now, enabling since 1990. This network enables~~ detection of long-term trends, validation of other data sets and models (De Mazière et al., 2018). There are six NDACC FTIR instruments within the Arctic: Ny-Ålesund, Eureka, Kiruna, Harestua, St-Petersburg and Thule, see Table 2. These instruments are Bruker high-resolution ( $< 0.005\text{cm}^{-1}$ ) spectrometers. The retrieval strategy used at all these sites is standardized by the InfraRed Working Group (IRWG) (IRWG, 2025). It has been recently updated from the previous version described in details in Vigouroux et al. (2015) to an improved strategy (IRWG2023),  
115 based on the HITRAN2020 molecular spectroscopic database (Gordon et al., 2022), specific spectral microwindows (around  $1000\text{cm}^{-1}$ ) fitted to avoid interference with water vapor lines, an updated regularization scheme (Tikhonov) and an updated a priori (WACCMv7 IRWG (IRWG, 2025)). More details on this new strategy used here can be found in the Appendix of ~~(Björklund et al., 2024)~~Björklund et al. (2024), where it was ~~found shown~~ to reduce biases with other instruments in Lauder, New Zealand from 1 – 3% for all partial columns as well as to reduce drifts.

120 In addition, we consider a new ozone time series (Kivi et al., 2026) obtained by applying a new retrieval (in the  $3040\text{cm}^{-1}$  region following the strategy of Zhou et al. (2020) and García et al. (2014)) to spectra recorded by the Sodankylä instrument that is part of the Total Carbon Column Observing Network (TCCON). The resulting vertical profiles contain lower DOFS of about 2.5, concentrated on the stratospheric layers, see Table 1.

	Random (%)	Systematic (%)	Total (%)	DOFS NDACC	DOFS Sodankylä
<b>0-8km</b>	5.43	6.19	8.57	0.89	0.07
<b>8-17km</b>	3.49	4.27	5.77	1.06	0.72
<b>10-17km</b>	4.26	4.15	6.27	0.89	0.67
<b>17-26km</b>	3.30	4.10	5.40	1.07	0.92
<b>26-48km</b>	3.87	6.35	7.53	1.28	0.68
<b>32-48km</b>	6.68	8.61	11.03	0.82	0.24
<b>TCO</b>	1.38	3.46	3.80	4.40	2.38

**Table 1.** Mean FTIR random, systematic and total uncertainties in percent and average degrees of freedom of signal (DOFS) of NDACC FTIR and of Sodankylä FTIR for each partial column and the total column of ozone (TCO).

For all time series, the uncertainty on ozone partial columns is obtained from the propagation of the retrieved profile uncertainties. Random and systematic uncertainties are themselves obtained using optimal estimation (Rodgers, 2000; Vigouroux et al., 2015). The random error of partial columns additionally contains a smoothing error (Rodgers, 2000) estimated from the WACCMv7 covariance matrix at each site. In Table 1 we provide the mean of the obtained uncertainties in percent for each partial column considered in this paper and the total column of ozone (TCO). The partial columns are based on FTIR DOFS that are explicitly given here for NDACC products and for the Sodankylä product.

## 2.2 Ozonesondes

Ozonesondes are small, light-weight devices flown on weather balloons that measure the vertical profile of ozone based on the titration of ozone in a neutral buffered potassium iodide sensing solution, with a precision better than  $\pm(3-5)\%$  and an accuracy of about  $\pm(5-10)\%$  for up to 30 km altitude (Smit et al., 2024). However, changes in preparation and operation procedures, manufacturer type, sensing solution strength, and processing might result in biases in the time series, compromising any reliable ozone trends assessment. Therefore, a homogenization activity, correcting for those biases following recommendations in [Smit and the ASOPOS 2.0 Panel \(2021\)](#); [Smit and the O3S-DQA Panel \(2012\)](#) ([Smit and the ASOPOS 2.0 Panel, 2021](#); [Smit and the O3S-DQA Panel, 2012](#)) has been undertaken, with all the homogenized ozonesonde data stored and described within the framework of the Tropospheric Ozone Assessment Report Phase II (TOAR-II) Focus Working Group HEGIFTOM (Harmonization and Evaluation of Ground-based Instruments for Free-Tropospheric Ozone Measurements, see also Van Malderen et al. (2025a)). In that study, the data from the Canadian Arctic sites Resolute, Alert, and Eureka and the European Arctic sites Scoresbysund, Ny-Ålesund, Sodankylä and Lerwick have been used. More details on the specific homogenization steps needed to correct those data sets are provided in Tarasick et al. (2016) for Resolute, Alert, and Eureka and in Nilsen et al. (2024) for Scoresbysund, Ny-Ålesund, and Sodankylä.

In this study, we cap sondes profiles at 26 km so that the mid-stratospheric column contains at least 60% of all measured profiles at all sites (in some sites such as Alert and Resolute, less than 50 to 40% of profiles reach up to 30 km because the sondes balloon burst before that altitude). We sum profiles over the partial columns defined ~~lower~~ below in Section 2.4. Random measurement uncertainties on profile points are also propagated to obtain partial columns uncertainties. When a profile doesn't provide uncertainties, we use the mean uncertainties of other profiles from the same site. Extreme outliers are found in the data after summing the profiles into partial columns. They are removed by applying a very loose percentile filter: for  $q_1$  and  $q_3$  the 25th and 75th percentiles, we remove datapoints lying beyond  $q_3 + 8(q_3 - q_1)$  or below  $q_1 - 8(q_3 - q_1)$  for each partial column time series.

### 2.3 Brewer and Dobson spectrophotometers

Brewer and Dobson spectrophotometers use UV light (about 305 – 340nm) to extract the total column of ozone by comparing relative intensities for pairs of selected wavelengths. All Brewer and Dobson total column data sets used in this study are obtained from the World Ozone and Ultraviolet Radiation Data Centre (WOUDC), one of six World Data Centres part of the Global Atmosphere Watch programme of the World Meteorological Organization. It provides total column ozone and vertical profile data from over 500 registered stations (<https://woudc.org/>). We use Brewer total column measurements from Resolute, Sondrestrom, Alert, Eureka, Vindeln, Oslo, Andoya and Dobson total column measurements from Lerwick, Barrow, Reykjavik, Fairbanks and Vindeln. They are given as daily measurements obtained from several measurements averaged together with a standard deviation estimate. When the standard deviation is not provided, we use a generic random error of 1% for direct sun observation (DS) and 5% for other types of measurement (zenith-sun ZS, focused-moon FM) (see e.g., Fioletov et al., 2005; Vogler et al., 2007). The Brewer in Alert has calibration issues concerning ZS measurements so these are excluded from the dataset. For all Brewer measurements we restrict to airmass factors  $\mu < 3.5$  for single monochromator instruments (MKII, MKIV and MKV). Finally, most stations have measurements taken by several instruments, so we average all same-day observations with a weighted mean.

### 2.4 Choice of partial columns

While Dobson and Brewer data sets only provide a total column measurement of the ozone abundance, ozonesondes and FTIR present vertically-resolved profiles. Since this vertical resolution only contains four to five ~~degrees of freedom~~ DOFS for the FTIR, we divide the troposphere and stratosphere into four layers (see Table 3) to obtain four partial columns of ozone, each containing about one DOFS for the FTIR (see Table 1). The specific choice of boundaries for these layers reflects the need for merging FTIR with sonde data sets.

~~During Winter, the tropopause in the Arctic typically lies at 8 km, but this value can become larger with seasons. To ease comparison to satellite products~~ Since we work with fixed altitudes defining partial columns boundaries, we do not follow the tropopause variations in time. Note that since FTIR provides low-resolution profiles, a clear-cut disentanglement of tropospheric and lower-stratospheric measurements is impossible and some mixing is necessarily present. The choice of 0-8 km reflects the averaged Arctic tropopause limit while satisfying the constraint on FTIR DOFS.

Site	Lat. °N	Lon.	Instr.	Repository	Time period
Alert	82.49	62.34°W	Sonde	HEGIFTOM	2000 – 2024

**Table 2.** Summary of all the ground-based data sets that have been considered in this study ordered by decreasing latitude.

\* Resolute’s is restricted to the 2005 – 2024 time period for reason detailed in the comparison with satellites, see section 3.

<sup>†</sup> Scoresbysund’s time series is not used at all in the trend analysis for reasons also detailed in section 3.

<sup>‡</sup> In the lower stratosphere, St-Petersburg’s is not used in the trend analysis because it cannot be merged with other data sets there and it only starts in 2009.

	<b>Troposphere</b>	<b>Lower stratosphere</b>	<b>Mid-stratosphere</b>	<b>Upper stratosphere</b>	<b>Total column</b>
<b>Layer(km)</b>	0 – 8 <u>km</u>	8 – 17 <u>km</u>	17 – 26 <u>km</u>	26 – 48 <u>km</u>	0 – 60 <u>km</u>
<b>CAMS grid</b>	1000 – 300 hPa	300 – 100 hPa	100 – 20 hPa	20 – 1 hPa	TC product
<b>Data sets used</b>	FTIR*, Sondes	FTIR, Sondes	FTIR, Sondes	FTIR	FTIR*, Brewer, Dobson

**Table 3.** Altitude layers defining the four partial columns of ozone considered for ozonesondes and FTIR. Partial columns are calculated from profiles using the altitude in kilometers. The CAMS grid line reports the approximate equivalent pressure layers used for calculating partial columns of CAMS data in the representativeness study (see section 4). The last line summarizes which data sets are used in each partial column of this study. The asterisk next to FTIR means that the lower-resolution product at Sodankylä is excluded.

In addition to the partial columns defined in Table 3, we consider an alternative lower stratospheric column from 10 – 17 km in section 3 ~~–An additional to ease comparison to satellite products, plus another~~ upper stratospheric column from 32 – 48 km ~~is also considered for trends~~ in section 5 ~~–in order~~ to better compare with trend literature that often considers the upper  
180 stratospheric layer higher up, ~~especially for satellite’s trends~~.

From those ozone columns we first calculate daily mean time series, and from those we obtain monthly mean time series. We then use the monthly mean time series to calculate relative (1) and absolute (2) anomalies:

$$\text{anom}^{\text{month}_x, \text{year}_y} = \frac{O_3^{\text{month}_x, \text{year}_y} - O_3^{\text{month}_x}}{O_3^{\text{month}_x}}; \quad (1)$$

$$\text{abs. anom}^{\text{month}_x, \text{year}_y} = O_3^{\text{month}_x, \text{year}_y} - O_3^{\text{month}_x}; \quad (2)$$

185 with

$$O_3^{\text{month}_x} = \frac{1}{n+1} \sum_{y=\text{start year}}^{\text{start year}+n} O_3^{\text{month}_x, \text{year}_y}, \quad (3)$$

the ozone mean for each month of the year averaging over  $n$  years of each data set ~~entire period~~, from start year to start year +  $n$ . ~~We will later use those anomalies for~~ Using anomalies when merging different data sets ~~without worrying about possible biases or different starting and finishing dates.~~ instead of monthly means removes the issues related to merging biased data

## 190 3 Comparison with satellite ozone data sets

### 3.1 Satellite data sets and method

We use comparisons with two different satellite data sets, IASI-CDR and MEGRIDOP, to investigate the quality of all the ground-based time series described above and to evaluate the presence of drifts in satellites for the whole Arctic zonal mean ~~–~~ (i.e., a weighted mean of all ground-based stations datasets within the 60-90°N region), both in the total column and for each  
195 partial column defined in section 2.4.

The IASI-CDR dataset is a homogeneous ozone Climate Data Record (CDR) based on the Infrared Atmospheric Sounding Interferometer observations recently produced by EUMETSAT on behalf of AC SAF (AC SAF, 2025). The IASI-CDR

O<sub>3</sub> product has been validated in Boynard et al. (2025), who reported small total ozone biases (< 1-2%), tropospheric differences of 10-12%, and long-term drifts below 3% per decade. It accurately captures seasonal and interannual variability and highlights a decrease in tropospheric ozone, notably in the tropics and Europe. Here, ~~IASI-IASI-CDR~~ O<sub>3</sub> total columns are obtained from the combined AERIS Level-3 monthly IASI-A and B products, while partial IASI-CDR Metop-A (2007-2013) and Metop-B (2013-2024) products, called hereafter IASI-A+B (Clerbaux and Coheur, 2025a, b). Partial columns are derived from monthly-mean IASI-A+B-merged monthly mean gridded profiles computed from the AERIS Level-2 daily ~~products (Clerbaux and Coheur, 2025a, b)IASI-CDR Metop-A and B products as in Keppens et al. (2025), called IASI-AB below~~. Both data sets cover ~~2008~~2007–2024 and we use daytime observations only.

The Merged GRidded Dataset of Ozone Profiles (MEGRIDOP) (Sofieva et al., 2021) was generated using data from six limb and occultation satellite instruments (OSIRIS, GOMOS, MIPAS, SCIAMACHY, Aura MLS, OMPS-LP SNPP). We use the Level-3 gridded monthly time series from 2001 until 2024, which has a 10° lat. × 20° lon. horizontal resolution and a vertical coverage from 10 – 50 km.

Our aim here is not to validate the satellite products but rather to compare satellite and ground-based time series to diagnose potential problems related to the calculation of trends from those time series. Therefore, we do not time-collocate satellites and ground-based measurements but instead we compute drifts by comparing monthly deseasonalized relative anomalies, that will later be used for trends computations. The time series of satellites are spatially collocated within their respective spatial grid with the ground-based instruments locations listed in Table 2. To compare satellite and ground-based time series, we define the difference of anomalies in percent:

$$\text{diff}_{\text{sat-GB}}^i = (\text{anom}_{\text{sat}}^i - \text{anom}_{\text{GB}}^i) \cdot 100\%, \quad (4)$$

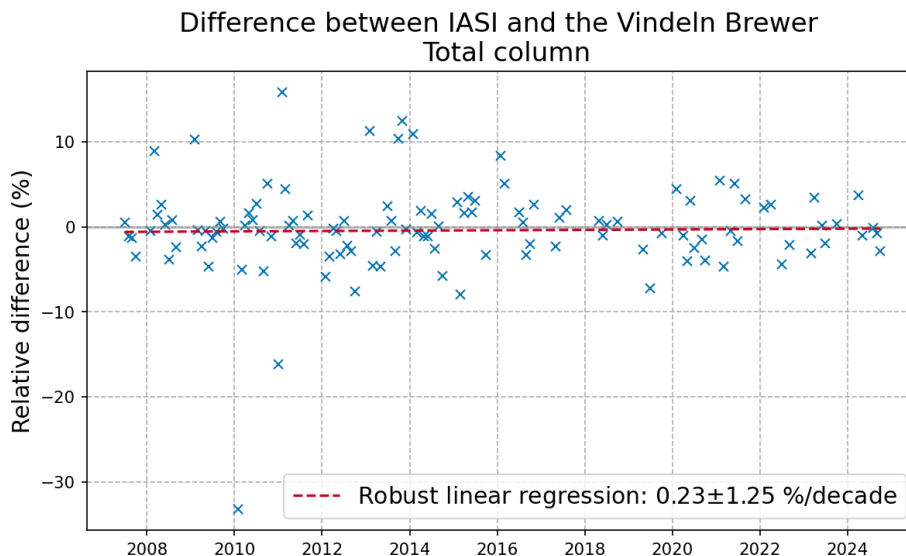

from which we obtain the relative bias and the scaled mean absolute deviation (MAD<sub>s</sub>) between the two time series (scaling with 1.4826 gives an equivalence to the 2σ of Gaussian statistics):

$$\text{bias} = \text{median}(\text{diff}_{\text{sat-GB}}^i); \quad (5)$$

$$\text{MAD}_s = 1.4826 \cdot \text{median}(|\text{diff}_{\text{sat-GB}}^i - \text{bias}|). \quad (6)$$

We then apply a robust linear regression (Theil-Sen method, (Sen, 1968)) on the difference  $\text{diff}_{\text{sat-GB}}^i$  (4) to obtain the trend of this difference, i.e., the drift and its associated error, as shown in Figure 2 for the Vindeln Brewer against ~~IASI-CDR-IASI-A+B~~ ozone total column.

The drift is estimated as the median of the slopes of all lines connecting all possible pairs of points. The ~~confidence interval for the drift estimate is given by the interval containing the middle 95% (to obtain an estimate of the standard Theil-Sen confidence interval estimates assume the time series have no autocorrelation, but by computing the autocorrelation on the regression residuals (as the Pearson correlation coefficient between the residuals at  $t$  and at  $t + 1$  (lag-1)), we find that 13% of our data sets have an autocorrelation comprised between 0.2 and 0.35 in absolute value. To rigorously account for this small autocorrelation, we have therefore applied the block bootstrap method (Gilda, 2024) to evaluate the confidence intervals of our estimated Theil-Sen drifts (Bontempi, 2024). We have used 1000 bootstrap samples and a block size of  $n^{1/3}$ , where  $n$  is the~~

**Figure 2.** Difference of relative anomalies in percent  $\text{diff}_{\text{sat-GB}}^i$  (4) between the Vindeln Brewer total column and the IASI-CDR-IASI-A+B total column in Vindeln with associated bias,  $\text{MAD}_s$ . The trend of this difference is represented by the red dashed line and corresponds to the drift, given in legend with its  $2\sigma$ -error. The presence of several strong outliers requires the use of a robust regression method, here the Theil-Sen method.

length of the dataset. The Theil-Sen method was applied on each bootstrap sample. The  $2\sigma$  error of those slopes. The drift error is then the maximum between the difference of the upper bound of the confidence interval with the median and the lower bound of the confidence interval with the median error estimate given for each drift value corresponds to the 95% confidence interval, calculated by multiplying the square root of the bootstrap estimate of variance by  $z = 1.96$ , i.e. the inverse of the standard normal cumulative distribution function  $F_N(z) = \alpha/2$ , where  $\alpha = 0.95$ .

235

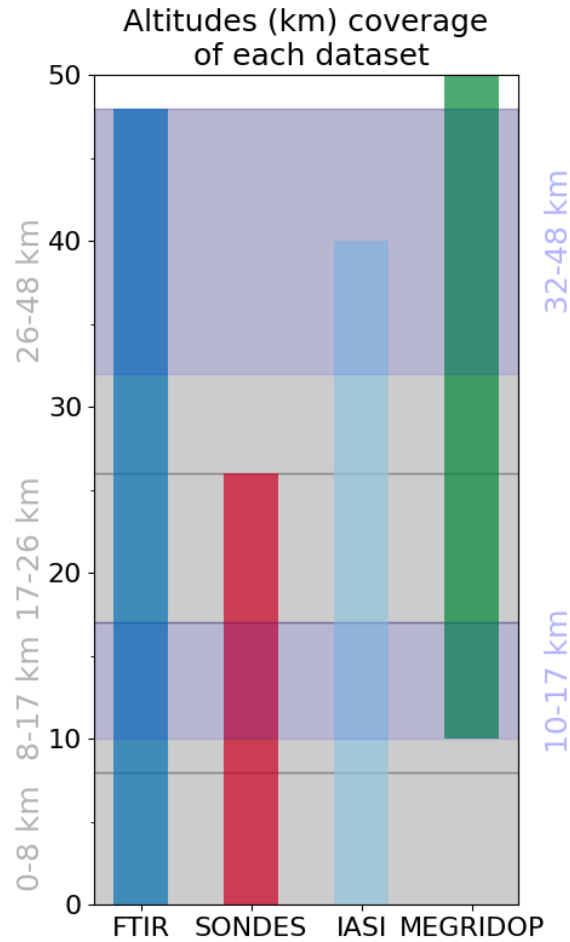

As explained before, we use the drift comparison in two ways. We make the assumption that problems in individual stations data sets can be identified by comparing to the two satellite data sets, while drifts in individual satellite dataset can be identified with combined ground-based data sets. In Section 3.2, we validate each individual ground-based dataset by spotting-detecting outliers in the drifts with respect to satellites, and then in Section 3.3, we evaluate satellites by computing their Arctic zonal band-mean drift with respect to the weighted mean of all validated ground-based time series.

240

### 3.2 Evaluation of ground-based time series from satellite comparison

MEGRIDOP is based on Limb satellites that do not measure in the troposphere, so ground-based measurements of the tropospheric column and the total column can only be compared to IASI-CDR (see Figure 3 for a visual representation of the vertical coverage of profile data sets versus the chosen partial column layers). Moreover, because MEGRIDOP only starts at 10 km, we consider an alternative lower stratospheric column from 10 – 17 km. This alternative lower stratospheric partial column can be

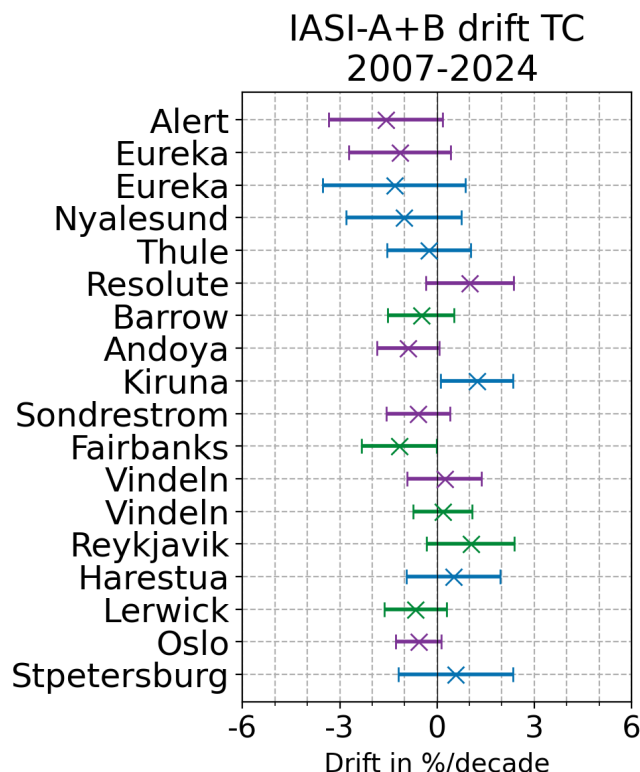

245

**Figure 3.** Vertical coverage in kilometers of each profile data sets used in this study against our choice for partial columns altitude boundaries in grey on the left. Additional alternative partial columns are shown in blue on the right. The choice of partial columns boundaries is explained in section 2.4.

easily computed and still retains enough DOFS for the FTIR (see Table 1). The reason why we selected 8 – 17 km as our main lower stratosphere column is because we want to be able to compare total column trends to the sum of partial column trends.

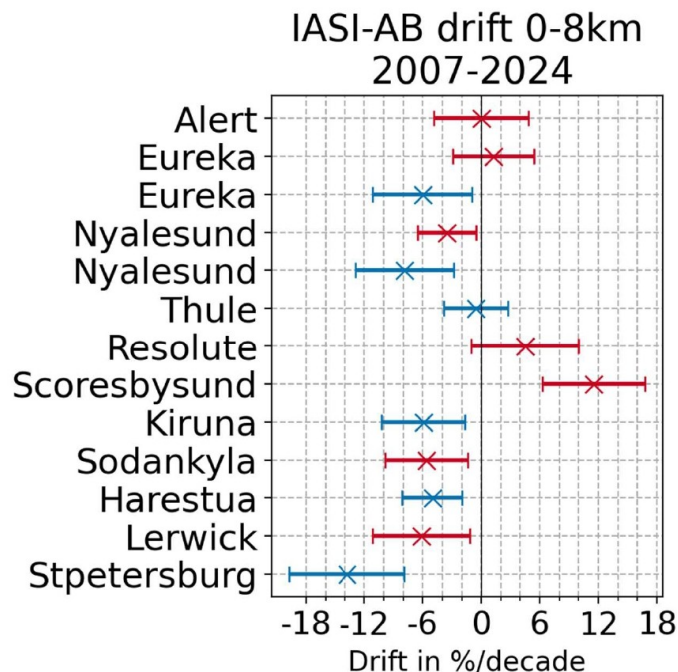

We do not identify any outliers in the total column ground-based time series. We find all drifts lay within  $|1.6\%/decade|$  (see Figure 4). Only the drifts in Fairbanks and [Alert Kiruna](#) are at the limit of  $2\sigma$  significance, reaching respectively  $(-1.17 \pm 1.06)$  and  $(-1.59 \pm 1.41)\%/decade$ . ~~Even though this  $(-1.17 \pm 1.16)$  and  $(+1.22 \pm 1.15)\%/decade$ . Although it~~ might indicate potential issues ~~around that time in those timeseries around 2007~~, we do not exclude ~~those time series them~~ from our trend analysis, as ~~these drift values are small and~~ we will in fact consider the full 2000 – 2024 period ~~and the drifts reported here are overall very small for trends~~.

**Figure 4.** Robust drift of IASI-CDR on the full 2007 – 2024 period for the total column with respect to all individual FTIR, Brewer and Dobson instruments in percent per decade, with a  $2\sigma$ -error. Instruments are ordered by decreasing latitude from top to bottom, and trends are color-coded depending on the instrument (purple: Brewer, green: Dobson, blue: FTIR).

In the troposphere, ~~see Figure 5, IASI-CDR exhibits a significant negative drift of at least  $-6\%/decade$   $-5\%/decade$  with seven of the ground-based instruments. This points toward an overall negative drift of IASI-CDR in the troposphere that we will comment on in Section 3.3. IASI-CDR is more negatively drifted with the St-Petersburg FTIR (about  $-14\%/decade$ ), but this dataset only starts in 2009. (see Figure 5).~~ The Scoresbysund sonde ~~however clearly stands out with a positive drift in IASI-CDR of  $(+11.51 \pm 3.58)\%/decade$ , significant beyond the  $5\sigma$  level, signaling a problem with this time series. stands out as the only significant positive drift of IASI, signaling an issue with this ground-based dataset. We checked that this large drift is not due to a different of time-sampling between the sonde data sets and the satellites: applying different filters on the minimal number of sonde measurements per month doesn't change the drifts values.~~

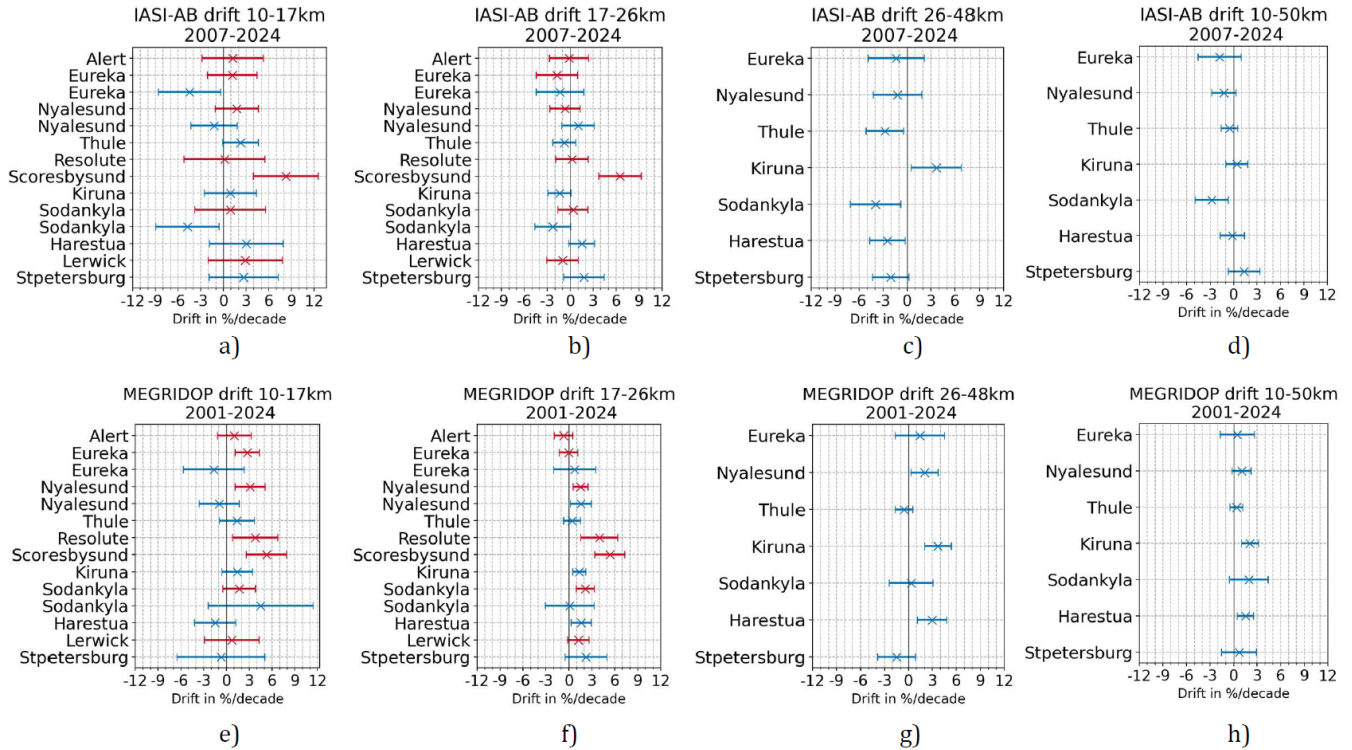

Turning to the stratospheric column drifts of both IASI (on the 2007-2024 period) and MEGRIDOP (on the 2001 – 2024 period) with respect to all individual ground-based instruments in Figure 6, we find that the Scoresbysund sonde also stands as an outlier in the lower and mid-stratosphere for both satellites. The drift is associated with a negative offset in the Scoresbysund ozone concentrations at most altitude levels in the ozonesonde time series since 2016 with respect to the previous years. Indeed,

**Figure 5.** Robust drift of IASI for the troposphere with respect to all individual FTIR and Sonde instruments in percent per decade with  $2\sigma$ -error. As in Figure 4, instruments are ordered by decreasing latitude from top to bottom, and trends are color-coded depending on the instrument (blue: FTIR, red: Sondes).

we have verified that the Scoresbysund’s sonde dataset does not show any significant drift with respect to MEGRIDOP over the prior 2001 – 2015 period, where we found a drift of about 4%/decade in the 10 – 17 km layer and of about 2%/decade in the 17–26 km layer, both non-significant. This drop in 2016 coincides with a change of ozonesonde type, ozonesonde pump battery type and radiosonde type, leading ~~resp.~~ respectively to a 3 – 4% bias in the ozone concentrations, lower pump temperatures (around –10K), and a possible offset in the atmospheric pressure measurements (switch from pressure sensor to GPS height-derived pressure measurements). The homogenization of the Scoresbysund time series at the HEGIFTOM repository only corrects for the first effect. The other two issues might be responsible for a drop in the ozone concentrations, e.g. too low pump temperatures might point to freezing solutions and too low signal readings and a shift of the entire profile with +1.5 hPa at mid-stratospheric pressure levels. Unfortunately, these issues need further investigation and adequate correction algorithms have not been developed yet, so we remove the Scoresbysund ozonesonde dataset from our study.

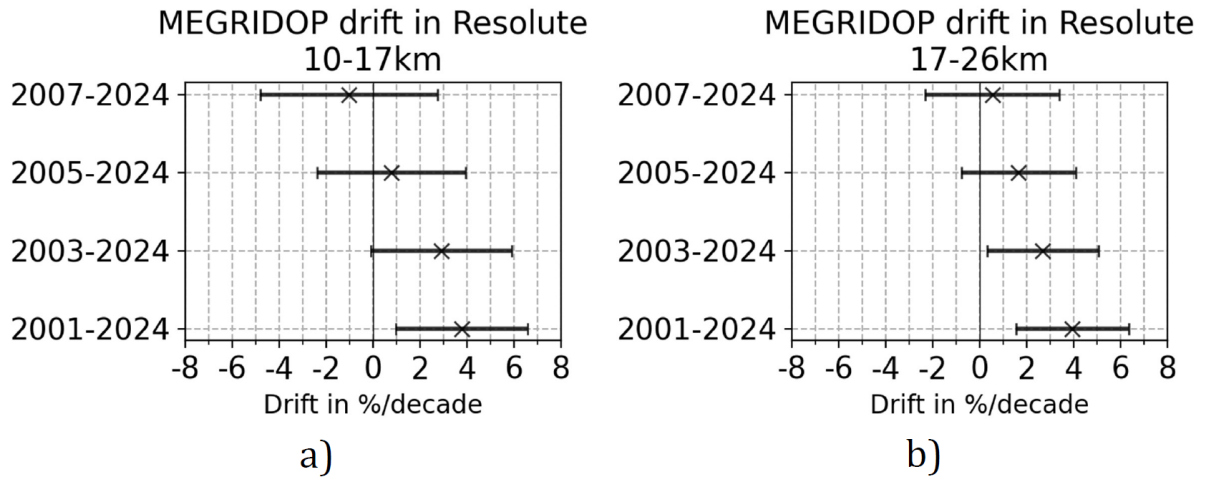

The Resolute sonde also appears as an outlier in MEGRIDOP’s drifts for the lower and mid-stratosphere but not in IASI-CDR’s drifts. By comparing the drifts on the same time period (2007 – 2024), the MEGRIDOP’s drifts at Resolute disappear, see Figure 7. In fact, we see a progressive diminution of the drift that becomes non-significant starting from 2005. This is probably the signal of a jump in the sonde dataset possibly due to instrumentation changes. Recalibrations in the data sets to account for these various changes have already been performed in Resolute (see [\(Tarasick et al., 2016\)](#) [Tarasick et al. \(2016\)](#))

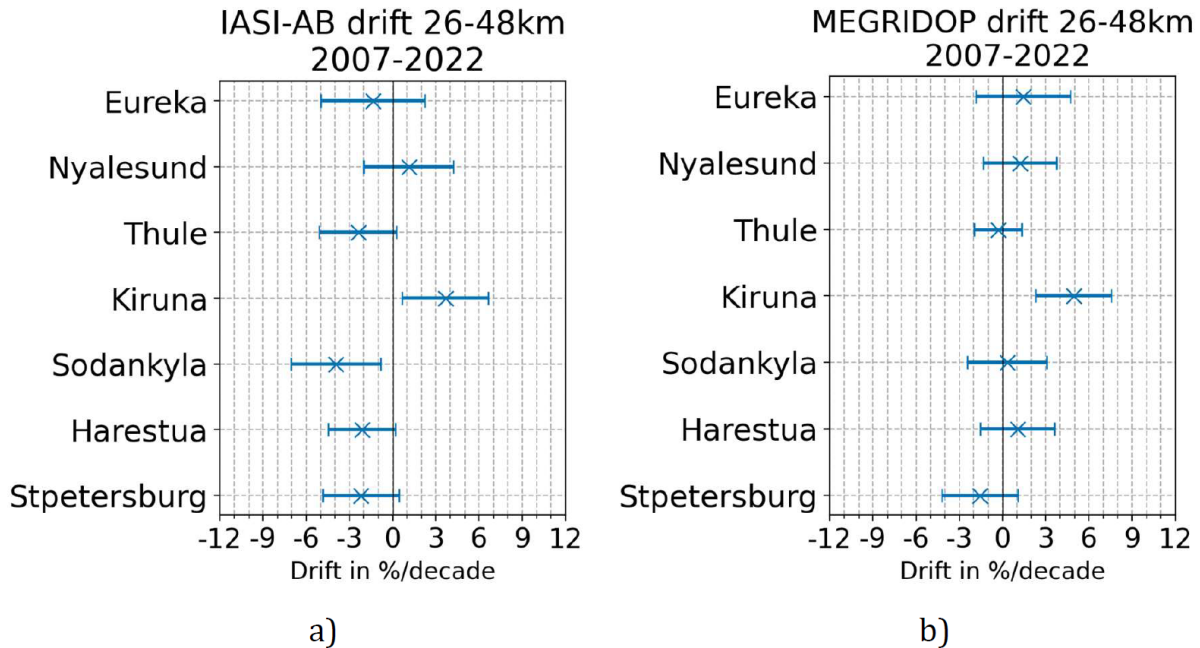

**Figure 6.** Robust drifts of IASI-CDR (a-d) and MEGRIDOP (e-h), with respect to ground-based measurements for stratospheric partial columns. Drifts are in percent per decade with  $2\sigma$ -error. Note that the time periods given in the title of each figure refers to the satellite time periods, but some ground-based time series are more limited, see Table 2.

but additional jumps cannot be excluded. Despite these recalibrations, it was found in Figure 17 of Tarasick et al. (2016) and Figure 3 of Nilsen et al. (2024) that the Resolute sonde exhibits stronger significant negative trends in the lower stratosphere than other sondes in the Arctic (except for the Churchill sonde that lies [below our 60°N limit equatorward](#)). To avoid effects of this potential jump, we consider the Resolute sonde dataset only starting from 2005.

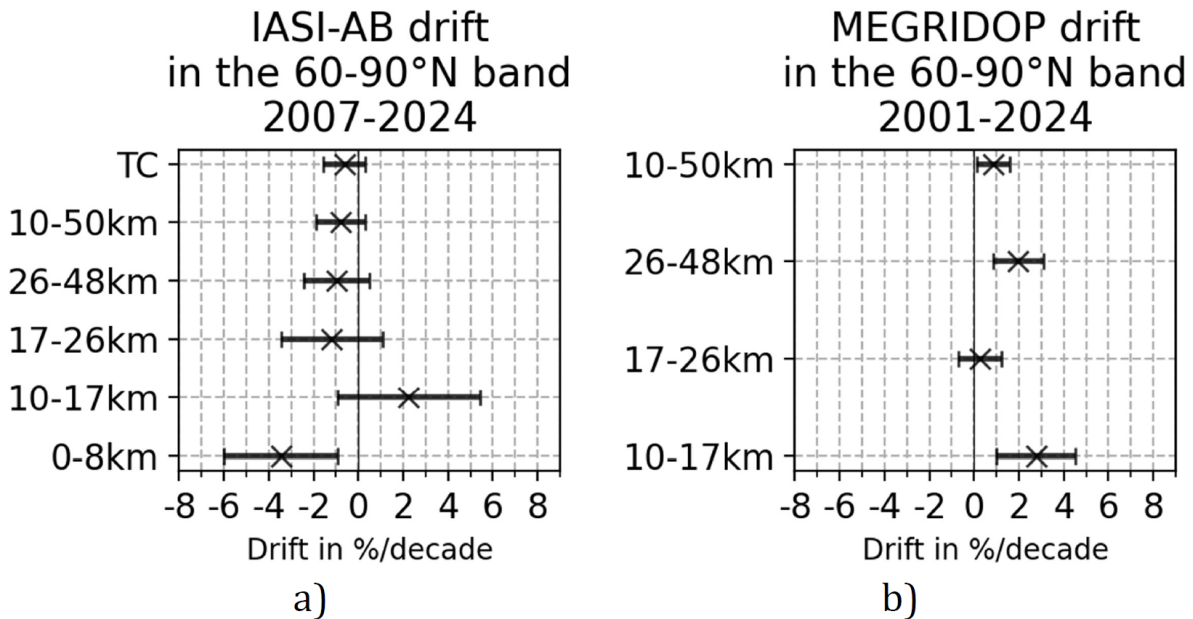

285 In the upper stratosphere (26–48 km, Fig. 6), IASI-CDR possesses small negative drifts everywhere except at Kiruna, where it shows a singular significant positive drift above 3%/decade. The drift of MEGRIDOP in Kiruna doesn't particularly stand out on the 2001–2024 period, but if we restrict both satellites to the same 2007–2022 time period (Kiruna time series stops in 2022, see Table 2), we observe a similar pattern where all drifts are non-significant and within 3%/decade except in Kiruna where they reach  $(3.56 \pm 2.31)\%/decade$   $(3.65 \pm 2.97)\%/decade$  for IASI-CDR and  $(4.91 \pm 2.08)\%/decade$   $(4.92 \pm 2.58)\%/decade$  for  
 290 MEGRIDOP, see Figure 8. There are no records of possible issues with the Kiruna FTIR time series and visual scrutiny of its monthly mean and anomalies time series doesn't reveal obvious jumps. As the drift value with MEGRIDOP using the full time series (Fig. 6) is comparable to other FTIR stations (although significant at Kiruna), we retain Kiruna for our trend analysis on the full time period.

**Figure 7.** Variation of the drift of MEGRIDOP with respect to the Resolute sonde in the lower (a) and mid (b) stratospheric columns, depending on the starting date of comparison.

**Figure 8.** Drifts of IASI-CDR (a) and MEGRIDOP (b) with respect to the FTIR data sets in the upper stratosphere when restricting to a common period of 2007 to 2022.

**Figure 9.** Drifts of satellites with respect to the zonal (weighted) means of all ground-based instruments in each column. Ground-based instruments with identified problems (Scoresbysund sonde, Resolute sonde before 2005) are not included in the means.

Finally, in the total stratospheric column (10 – 50 km, Fig. 6), IASI-CDR does not exhibit any significant drift except with [Sodankylä FTIR](#) [the FTIR at Sodankylä](#). That time series is retrieved from a different spectral range than other NDACC FTIR products but there is no trace in previous studies of a potential drift due to this method of retrieval (García et al., 2014; Zhou et al., 2020). It is also the only time series that starts in 2012 so the starting date for IASI-CDR comparison is different from all other data sets.

### 3.3 Drift of satellites for the Arctic zonal [band mean](#)

Having set aside [problematic](#) ground-based time series [with identified problems](#), we average all remaining [ones data sets](#) by a weighted mean (weights are given by the inverse squared uncertainties), and compare this average with the mean of satellites time series at the site locations. The resulting zonal [band mean](#) drifts of IASI-CDR and MEGRIDOP are presented in Figure 9.

The zonal mean drift of IASI-CDR total column is of  $(-0.63 \pm 1.01)\%/decade$   $(-0.62 \pm 0.94)\%/decade$ . This is a very small uncertainty and it shows that the IASI-CDR Level 3 AERIS total column product [is not drifted](#) [doesn't show a drift](#) over its full time series.

In the troposphere we find [that IASI-CDR has](#) a negative significant drift of  $(-3.47 \pm 2.35)\%/decade$ . [This can be explained by the sensitivity drop of IASI-CDR at high latitudes, especially of  \$\(-3.47 \pm 2.54\)\%/decade\$ . Since the sensitivity of IASI in the troposphere is low, with an average number of DOFs < 0.45, the a priori has a strong influence on the retrieved measurements](#) in the troposphere. [By computing the trace of the averaging kernels of IASI-CDR troposphere profiles at our 16](#)

310 ~~Degrading the ground-based stations locations, we find it contains on average about 0.4 DOFS (see also Boynard et al. (2025)).~~  
~~A more precise determination of the IASI-CDR tropospheric drift would require to smooth out the ground-based measurements~~  
~~to the IASI-CDR sensitivity prior to comparison~~ data sets to the IASI sensitivity by smoothing their profiles with the IASI  
averaging kernels (Rodgers and Connor, 2003) was found to shift the IASI drift by  $-2.3\%/decade$  on average in the Arctic  
troposphere in Boynard et al. (2025). However, the smoothing formula must be performed on each individual profiles: the  
315 ~~averaging kernel are non-linear objects and smoothing averaged monthly data is not equivalent to averaging individually~~  
~~smoothed profiles, and can introduce additional errors. We therefore do not smooth the ground-based data sets here. This~~  
~~means that we probably underestimate the tropospheric IASI drift is by about 2%. Note that the much smaller drift obtained by~~  
~~Boynard et al. (2025) in the Arctic troposphere of  $(-1.5 \pm 1.8)\%/decade$  is biased due to the use of the Scoresbysund sonde~~  
~~dataset in the validation, see the Table S1 of Boynard et al. (2025) with individual stations drifts. By excluding this dataset~~  
320 ~~and including FTIR, we find a larger and significant drift of the IASI Arctic troposphere. A more detailed validation using~~  
~~time-located pairs of smoothed Level-2 measurements is necessary to evaluate the exact amplitude of this drift and whether~~  
~~it represents a real stability issue.~~

IASI-CDR doesn't show any significant drift in the lower, middle and total stratosphere. In the lower stratosphere the  
individual drifts are all within  $|5\%/decade|$  (with a zonal mean drift ~~within  $3\%/decade$~~  of  $(2.25 \pm 3.17)\%/decade$ ), and in  
325 the middle and total stratosphere individual drifts lay within  $|3\%/decade|$  (with a zonal mean drift ~~within  $1.5\%/decade$  and~~  
 ~~$1\%/decade$~~  of  $(-1.19 \pm 2.26)\%/decade$  and  $(-0.79 \pm 1.12)\%/decade$  respectively).

~~In the upper stratosphere, despite a negative significant drift at four individual stations, the zonal band drift of IASI-CDR~~  
~~is non-significant and only about  $1\%/decade$ . Even if we exclude Kiruna (which is driving the mean to more positive values),~~  
~~that drift stays non-significant and reaches  $(-1.42 \pm 1.62)\%/decade$ .~~

330 MEGRIDOP is positively drifted with respect to the zonal mean of all ground-based instruments in the lower and upper  
stratosphere with drifts of  $(2.76 \pm 1.48)\%/decade$  and  $(1.97 \pm 0.97)\%/decade$  ( $(2.76 \pm 1.77)\%/decade$  and  $(1.97 \pm 1.18)\%/decade$   
respectively. The smallness of ~~these uncertainties is however remarkable, especially when considering the high variability of~~  
~~individual drifts in the lower stratosphere for instance~~ the uncertainties reinforces our assumption that the zonal mean drift  
captures the true satellite drifts, while averaging out individual ground-based instruments errors and drifts.

335 In the mid-stratosphere, the zonal ~~band mean~~ drift of MEGRIDOP is ~~smaller than  $1\%/decade$~~  only  $(0.27 \pm 0.96)\%/decade$   
while all individual drifts lay within  ~~$3\%/decade$~~   $|2.3\%/decade|$ .

Finally, in the total stratospheric column, MEGRIDOP's zonal ~~band drift lies at the limit of significance:  $(-0.87 \pm 0.82)\%/decade$~~  mean  
drift is slightly positive significant:  $(0.88 \pm 0.73)\%/decade$ . All individual drifts are ~~also within  $3\%/decade$~~  within  $|2.1\%/decade|$ .  
The smallness of the uncertainty is here also remarkable, but is expected to be smaller in MEGRIDOP than for IASI-CDR since  
340 the time period of comparison is more extended.

### 3.4 Conclusions on ground-based versus satellite comparisons

1. The Scoresbysund sonde is strongly negatively drifted. The drift is probably associated with ~~ample the many~~ instrumental  
changes around 2016 that cannot be fully corrected for. ~~This is important as this sonde was used in the past for validation~~

of satellites whose drift could have been overestimated or underestimated accordingly, as in Boynard et al. (2025). We

345 don't use this time series in our trend analysis.

2. We find hints of a potential jump in the Resolute sonde dataset before 2005, possibly due to instrumentation changes. We restrict this time series to 2005 – 2024 for the trend analysis.

3. ~~For the whole Arctic zonal band~~In the Arctic zonal mean, both satellites drifts are smaller than  $|3\%/decade|$  for all stratospheric columns.

350 4. IASI-CDR ~~only appears significantly drifted~~possesses a significant drift only in the troposphere, where its zonal ~~band drift reaches  $(-3.47 \pm 2.35)\%/decade$ , but IASI-CDR's low tropospheric sensitivity has not been accounted for. Moreover, this drift is close to the  $3\%/decade$~~ mean drift reaches  $(-3.47 \pm 2.54)\%/decade$  without smoothing. The effect of smoothing cannot be applied on monthly averaged measurements trustfully, but has been shown to shift the drift by  $-2.3\%/decade$  on average in the Arctic troposphere (Boynard et al., 2025). A careful validation on time-located smoothed Level-2 measurements is necessary to determine if this drift indeed exceeds the stability threshold of tropo-  
355 ~~spheric ozone (Weber, 2024), making it marginally stable. Additional years of monitoring are necessary to enable a definitive conclusion about this product stability.~~

5. MEGRIDOP shows significant positive drifts for the zonal ~~band-mean~~ in the lower, upper and total stratosphere of  ~~$(2.76 \pm 1.48)$ ,  $(1.97 \pm 0.97)$  and  $(0.87 \pm 0.82)\%/decade$~~  $(2.76 \pm 1.77)$ ,  $(1.97 \pm 1.18)$  and  $(0.88 \pm 0.73)\%/decade$  re-  
360 spectively. These values, and in particular their very small associated uncertainties, constitute important results concerning the stability of the MEGRIDOP product, which is used in the Long-term Ozone Trends and Uncertainties in the Stratosphere (LOTUS) initiative.

#### 4 Representativeness study

An important drawback of ground-based measurements of atmospheric species compared to satellites measurements is the  
365 coarse spatial coverage of the data. Despite the use of various instrument types, in this study we only consider sixteen different sites where ozone is measured over a sufficiently long time period, spanning a region from 60 to 90°N, equivalent to a surface area of 34 million ~~kilometers square~~square kilometers. On the other hand, the long-term trends we are trying to observe are known to be small and ~~drowned out by~~hiding behind the large natural variability of ozone in the Arctic. To reduce uncertainties and obtain statistically significant trends, it is advantageous to combine several data sets which are geographically close. But  
370 what is a good criterion to combine data sets together? And what will be the spatial extent that the trends obtained from these combined data sets can actually represent? To answer these questions, we perform a representativeness study following Weatherhead et al. (2017). A similar representativeness study based on CAMS data for ozone but limited to the troposphere was also conducted in Van Malderen et al. (2025b). We use the CAMS global reanalysis (EAC4) monthly averaged fields (Inness et al., 2019) of ozone to calculate the correlation of ozone time series between the locations of each of our ground-  
375 based stations. This assumes that correlations are not only due to inter-annual variability, but that since we are comparing

the same variables (i.e., ozone anomalies) at different locations, the same physical processes are causing the variability, so that similar trends are expected for largely correlated locations. This enables us to define groups of stations that are highly correlated, and for which we create merged ground-based data sets whose trends are studied in section 5. We further refine the regional representativeness of those groups of ~~station-stations~~ by calculating the correlations of CAMS ozone time series at those stations with CAMS ozone time series in the rest of the Arctic. The CAMS dataset is a gridded dataset with a global coverage, a spatial resolution of  $0.75^\circ \times 0.75^\circ$  and a temporal coverage from 2003 – 2024. We use the ozone total column and the vertically gridded ozone profile given in 25 pressure levels that we sum in four partial columns as shown in Table 3.

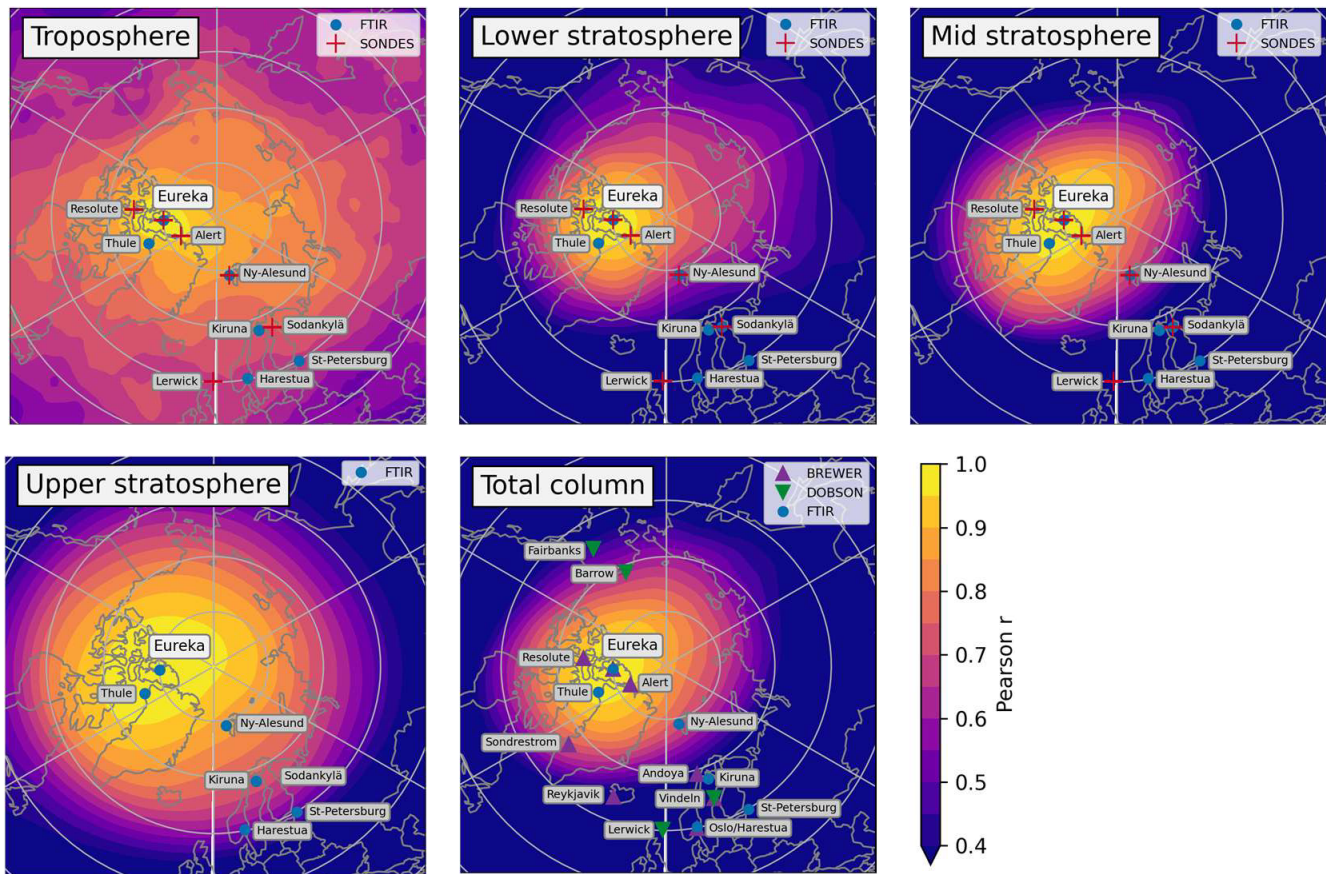

Correlations are calculated based on monthly ~~deaseasonalised~~ deseasonalized absolute anomaly (Eq. (2)) time series because correlations of ozone column time series would mostly reflect the seasonal cycle of ozone. Therefore, the correlations represent the similarity in ozone variability independent of the seasonal cycle. For each ground-based station, we ~~thus~~ compute the Pearson correlation coefficient  $r_{x,y}$  between the CAMS monthly anomaly at the grid-cell where that site is located,  $x$ , and the CAMS monthly anomalies for each of all the other cells,  $y$ , located in Arctic (60-90°N):

$$r_{x,y} = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}}; \quad (7)$$

where  $x_i$ ,  $i \in (1, \dots, n)$  is the time series of ozone at the site location  $x$ ,  $\bar{x}$  is the mean of that time series, and similarly for  $y$  at all other locations of the grid. We have verified the consistency of our results by analyzing the scatterplots of absolute anomalies between each ground-based station location.

We obtain correlation maps (see Figure 10) at each ground-based station for the total column and the four partial columns of ozone. We consider each of these columns separately in this analysis because they all entail different sets of ground-based instruments (see Table 3) but also because the atmospheric dynamics and ozone chemistry vary with altitude, impacting the size of correlated regions in each layer. In the lower and mid-stratosphere (8-26 km), we find that regions with correlated ozone anomalies are smaller in extent than in the upper stratosphere, above 26 km. This is expected since photochemistry drives ozone variability in the upper stratosphere, while in the lower and mid-stratosphere, dynamical activity dominates variability (Brasseur and Solomon, 2005). In the troposphere, very highly correlated regions ( $r > 0.95$ ) are small like in the lower stratosphere, but correlated regions with  $r \in [0.6, 0.9]$  are very spread out. This is consistent with the fact that photochemical processes dominate ozone variability in the troposphere (Cooper et al., 2014) and that emissions of ozone precursors are low and relatively homogeneous across the  $70^\circ - 90^\circ\text{N}$  region.

From CAMS correlation maps, we define our groups of stations: within one group, the CAMS correlation of each member station with each other member stations must be higher than  $r > 0.8$  (in Weatherhead et al. (2017), correlations of  $r > 0.7$  are deemed "well correlated", while  $r > 0.9$  are "strongly correlated"). Correlations between all stations are given in the Appendix in Figure A1 and A2. The resulting regional groups are presented in Table 4. Some stations stand on their own and do not correlate well with any other stations. We consider them in our trend study only if their time series spans most of the 2000–2024 time period. For instance, Reykjavik and Sondrestrom in the total column are considered for trends, while St-Petersburg in the lower stratosphere and total column is not.

**Figure 10.** Correlation of CAMS deseasonalized anomalies at the location of the Eureka station with CAMS anomalies in the rest of the Arctic for the 4 partial columns and the total column of Table 3. Stations where a ground-based instrument is used in the corresponding partial column are indicated.

Having defined the groups of stations whose time series will be combined in order to obtain trends with reduced uncertainties, we now determine the spatial regions for which these trends will be representative. A grid-cell on the map is part of a group's region if the correlation coefficients  $r$  of the grid-cell with each of the group's stations are all larger than 0.8. If a grid-cell is part of several regional groups, the prevalence goes to the group with the highest mean of correlations between each of its stations and the grid-cell. All regional groups for each atmospheric layer are depicted in Figure 11.

**Table 4.** For each atmospheric layer, this table lists all data sets (classified by instrument) comprised in each of the groups we determined using the representativeness study and which are pictured on the maps in Figure 11. Within a group, all station locations correlate with  $r > 0.8$ , see all correlations tables in the Appendix in Figures A1 and A2. Across layers, we have aligned groups corresponding to similar regions to represent how we can later sum partial column trends and compare with total column trends. For instance, the Canada total column trend will be compared to the sum of the North Pole tropospheric trend, the Canada lower and mid stratospheric trends and the North Pole upper stratospheric trend.

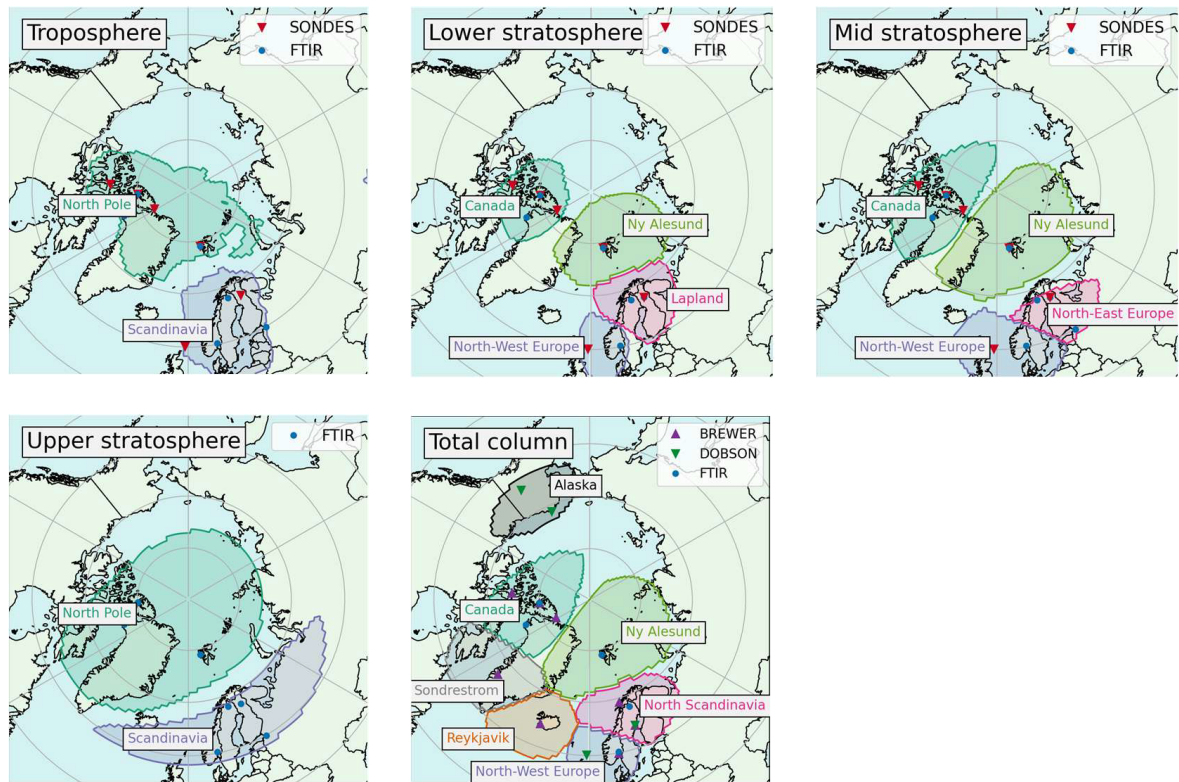

## 5 Regional trends

### 415 5.1 Merged data sets

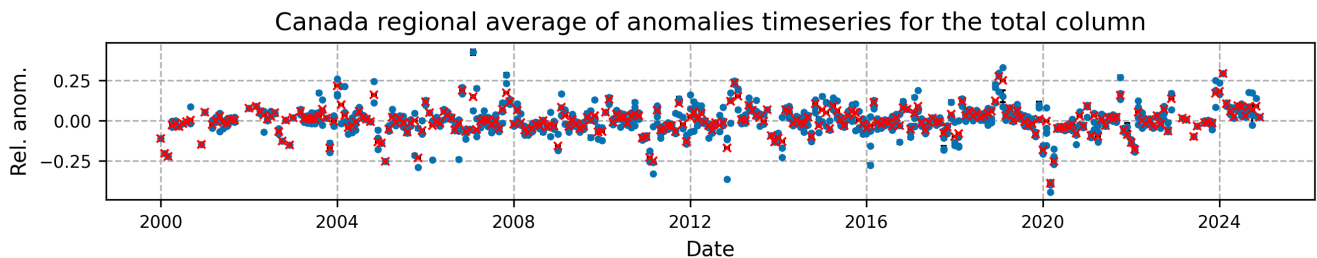

We calculate trends based on merged data sets obtained from weighted means of ozone anomalies (Eq. (1)) time series, see Figure 12 from an example with the total column anomalies of Canada. [All the resulting merged data sets are available on the BIRA-IASB repository \(Jonas and Vigouroux, 2026\).](#) Starting from  $N$  different anomalies data sets,  $\text{anom}_\alpha$ , their weighted merging is calculated as:

$$420 \quad \text{anom}_{\omega-m} = \frac{\sum_{\alpha=1}^N \omega_\alpha \text{anom}_\alpha}{\sum_{\alpha=1}^N \omega_\alpha}. \quad (8)$$

The weight used for merging is the inverse square of the anomalies errors,  $\omega_\alpha = 1/(\Delta \text{anom}_\alpha)^2$ . ~~But since~~ Since systematic errors are affecting all values of the timeseries in the same way, we ignore them when considering anomalies and we only propagate random measurement uncertainties (considered as statistically independent) into the daily and monthly means of ozone columns and the monthly ozone anomalies. Starting from the individual measurements random uncertainties of the ozone

**Figure 11.** Regional groups for the total column and each partial column, listed in Table 4. We don't consider the St-Petersburg station in the total column and the lower stratosphere because it stands on its own there but has a too short time series (2009 – 2024). In the upper stratosphere, Ny-Ålesund correlates equally well with Eureka and Thule as with Kiruna and Sodankylä. Since Kiruna and Sodankylä also correlate with Harestua and Lerwick, while the two latter do not correlate at all with Ny-Ålesund, we have chosen to include Ny-Ålesund with the Canadian sites.

**Figure 12.** Merged dataset of Canada total column's anomalies (red crosses) on top of all individual total column's anomalies data sets superimposed (blue dots) part of the Canada TC region, see Table 4.

Instrument	Column	$\Delta$ anomalies
Brewer	TCO	0.449 %
Dobson	TCO	1.067 %
FTIR	TCO	0.413 %
FTIR	0-8km	1.481 %
Sondes	0-8km	1.714 %
FTIR	8-17km	0.986 %
Sondes	8-17km	0.545 %
FTIR	17-26km	0.908 %
Sondes	17-26km	0.316 %
FTIR	26-48km	1.179 %

**Table 5.** Averaged random error for anomalies for each instrument and each ozone column

425 timeseries  $\Delta O_3^{\text{individual}}$ , we calculate the uncertainties on the daily means  $\Delta O_3^{\text{day}}$ , where  $N_{\text{day}}$  is the number of measurements in that specific day, and then we further propagate the random error to the monthly mean to obtain  $\Delta O_3^{\text{month}}$ , with  $N_{\text{month}}$  the number of days of measurement within that month:

$$\Delta O_3^{\mu=\{\text{day or month}\}} = \frac{1}{N_{\mu}} \sqrt{\sum_{\lambda=1}^{N_{\mu}} (\Delta O_3^{\lambda})^2}, \quad \text{with } \lambda = \{\text{individual or day}\} \text{ respectively.} \quad (9)$$

Finally, the error on the monthly relative anomalies (Eq. (1)) is given by:

$$430 \quad \Delta \text{anom}^{\text{month}_x, \text{year}_y} = \frac{1}{O_3^{\text{month}_x}} \sqrt{(\Delta O_3^{\text{month}_x, \text{year}_y})^2 + (O_3^{\text{month}_x, \text{year}_y} \cdot \Delta O_3^{\text{month}_x} / O_3^{\text{month}_x})^2}. \quad (10)$$

The random error on relative anomalies is given for each instrument and column in Table 5 in percent.

## 5.2 Regression model and proxies

Stratospheric ozone trends are expected to be small (within a few %/decade) while the natural ozone variability is especially high in the Arctic (Brasseur and Solomon, 2005; Langematz and Tully, 2018). This means a simple linear regression is not  
435 sufficient to detect long-term trends. In this work, trends are calculated with a multiple-linear regression (MLR) using nine different proxies summarized in Table 6. These proxies [try to](#) account for the natural variability of ozone, thus reducing trends uncertainties. The proxies are similar to those used by Vigouroux et al. (2015), except that for the processes included in the LOTUS MLR model (Petropavlovskikh et al., 2019), namely Solar cycle, QBO, and ENSO, we used the LOTUS prescribed data sets made publicly available within the OREGANO project (<https://www.iup.uni-bremen.de/OREGANO/proxydata/>). For  
440 Arctic Oscillation (AO) and Brewer-Dobson Circulation (BDC) proxies, we also use data sets provided within OREGANO, for

which the accumulation during Winter months has been taken into account (Weber et al., 2022). The Volume of Polar Stratospheric Clouds (VPSC) have been calculated as the volume of air between the 370 K and 550 K potential temperature levels, where the temperature is below the formation temperature of ICE or NAT clouds, using ERA5 temperature (Thölix, 2026). We assumed a formation temperature of 185 K for ICE clouds and 194 K for NAT clouds (Rex et al., 2004). We also take into  
445 account the accumulation during Winter following (~~Brunner et al., 2006~~) Brunner et al. (2006). The local proxies (tropopause pressure (TP), equivalent latitude (EL) and stratospheric temperature (T)) have been taken from ERA5 reanalysis at the location of each station. Then for each region, we use as final TP, EL, and T proxies the mean of these local proxies at the sites included in a single region (4). The EL and T proxies are calculated for the three stratospheric columns, leading to six proxy time series (called LS, MS, and US for the lower, middle and upper stratospheric columns, see Table 3). For each partial column, the mean  
450 of the EL (T) values in the corresponding ERA5 vertical layers is used. From all these proxies, only the local stratospheric temperature proxy is new compared to (~~Vigouroux et al., 2015~~) Vigouroux et al. (2015).

Since we use monthly anomalies (Eq. (1)) for the determination of the trend, all the proxies are also deseasonalized, ~~and~~,  
Note that proxies are not detrended as we want our trends to only reflect the influence of ODS changes. The effect of proxies detrending will be discussed below. For now, we model the monthly anomalies time series  $a(t)$  as:

$$455 \quad a(t) = A_1 + A_2 \cdot t + \sum_{n=3}^m A_n \cdot X_n(t) + \varepsilon(t), \quad (11)$$

where  $X_n(t)$  are the explanatory variables (i.e., proxies) with  $A_n$  their regression coefficient and  $A_2$  is the estimated trend. The trend error is given at the  $2\sigma$  level and multiplied by a specific factor to account for autocorrelation (see Santer et al. (2008), which presents an alternative to the Cochrane-Orcutt method). Finally,  $\varepsilon(t)$  is the residual (difference between the regressed model and the real data). Note that the regression coefficients can be either negative or positive.

460 For each trend calculated, a stepwise procedure determines the relevant proxies used in the regression (Mäder et al., 2007), which can differ by region and partial column. Each of those relevant proxies adds an individual contribution  $C_{\text{frac}}$  to the coefficient of determination  $R^2 = \sum C_{\text{frac}}$ . This individual contribution is calculated as the product of the standardized regression coefficient of the proxy with the correlation coefficient between the proxy and the observed dataset. The coefficient of determination then represents a statistical measure of the goodness of fit, i.e., how well the regressed model matches the data sets  
465 variability.

Let us now analyze in detail the total coefficients of determination  $R^2$  together with the individual contributions from each proxies for all partial columns, as depicted in the charts of Figure 13 for the annual trends of merged anomalies data sets. The reader is referred to the Appendix for similar charts of seasonal trends in Figure B1.

First we comment on the presence of proxies correlations. The temperature and equivalent latitude proxies are often cor-  
470 related (up to  $|r| = 0.8$  for the  $T_{\text{LS}}$  and  $T_{\text{MS}}$  in the total column) but thanks to the stepwise regression method, both can be included without overfitting. In cases where the stepwise procedure still selects two proxies with high correlation, we explicitly verify that their combined use positively improves the fitting of the model to the data sets (i.e., leads to a higher coefficient  $R^2$  without increasing the uncertainty on the trends). The median value of the absolute correlations between proxies is of about  $|r| = 0.15$ .

Process	Proxy used	Source
Solar cycle	Bremen composite Mg II index	<a href="#">OREGANO project</a>

**Table 6.** The nine proxies used in the MLR for attribution of ozone variability in ozone trends and their sources.

475 In all columns, the tropopause pressure (TP) doesn't contribute significantly to any of the merged regions but is relevant for the single-site regions, namely Ny-Ålesund, Reykjavik and Sondrestrom. The TP is largely influenced by the seasonal cycle and therefore strongly correlates with monthly ozone means (Hoinka et al., 1996; Steinbrecht et al., 1998), but a correlation still persists for deseasonalized anomalies (Coldewey-Egbers et al., 2022). The TP has sometimes been used as a proxy in single-site ozone trends (Vigouroux et al., 2015; Bernet et al., 2023). Because it reflects mainly local variability, in general it is not used when calculating satellite trends over zonal bands (Sofieva et al., 2021; Weber et al., 2022; Godin-Beekmann et al., 480 2022). The averaging of the TP time series over a region likely removes most of the correlations between ozone and TP at individual sites. However, a positive correlation between the ozone anomalies and the TP was found also for the North-Atlantic region in Coldewey-Egbers et al. (2022), so this feature may vary depending on location and region's size.

In the troposphere, the ~~values we obtain for the coefficient~~ [coefficients](#) of determination for annual trends are relatively 485 small ( $R^2 \leq 0.25$ ). ~~This is expected since the proxies used in this study are tailored to explain the variability of stratospheric ozone but do not capture the tropospheric ozone variability well.~~ The main contributing proxies in the troposphere are the Arctic Oscillation (AO) and the lower stratosphere temperature ( $T_{LS}$ ), and to a smaller extent the tropopause pressure (TP) and the solar cycle (Solar). The three former [might can](#) impact the troposphere via stratosphere-troposphere exchange. [In this study we haven't included specific proxies to account for the tropospheric ozone variability as our main focus was on the stratosphere-troposphere exchange. Overall, tropospheric ozone variability is delicate and poorly understood. It can depend on local chemical emissions and processes \(NO<sub>x</sub>, CO\), forest fires, vegetation changes, as well as large-scale weather patterns.](#) 490

Accounting for these processes requires the use of global long-term simulations as in Law et al. (2023) and lies beyond the scope of our study.

In the lower and mid-stratospheric columns, we find that the main proxies contributing to the coefficient of determination are the equivalent latitude (EL) and the temperature (T) of the corresponding stratospheric layer. We see that the volume of polar stratospheric cloud is also very important except in the North-West Europe region, most probably because this region latitude is too low (about 60° N). Other proxies as the QBO, Solar cycle, ENSO, AO and BDC are present but with small contributions. The coefficients of determination  $R^2$  are of about 0.4 for merged regions and 0.6 for the single-site region of Ny-Ålesund.

In the upper stratospheric column, we find again a predominance of the equivalent latitude and temperature proxies of that layer. The  $R^2$  value values are lower (0.2–0.35), with a marked diminution when considering the zonal band-mean (All Arctic). Note that for trends in the upper stratosphere, the VPSC proxy is not used, since polar stratospheric clouds form between 15 and 25 km of altitude.

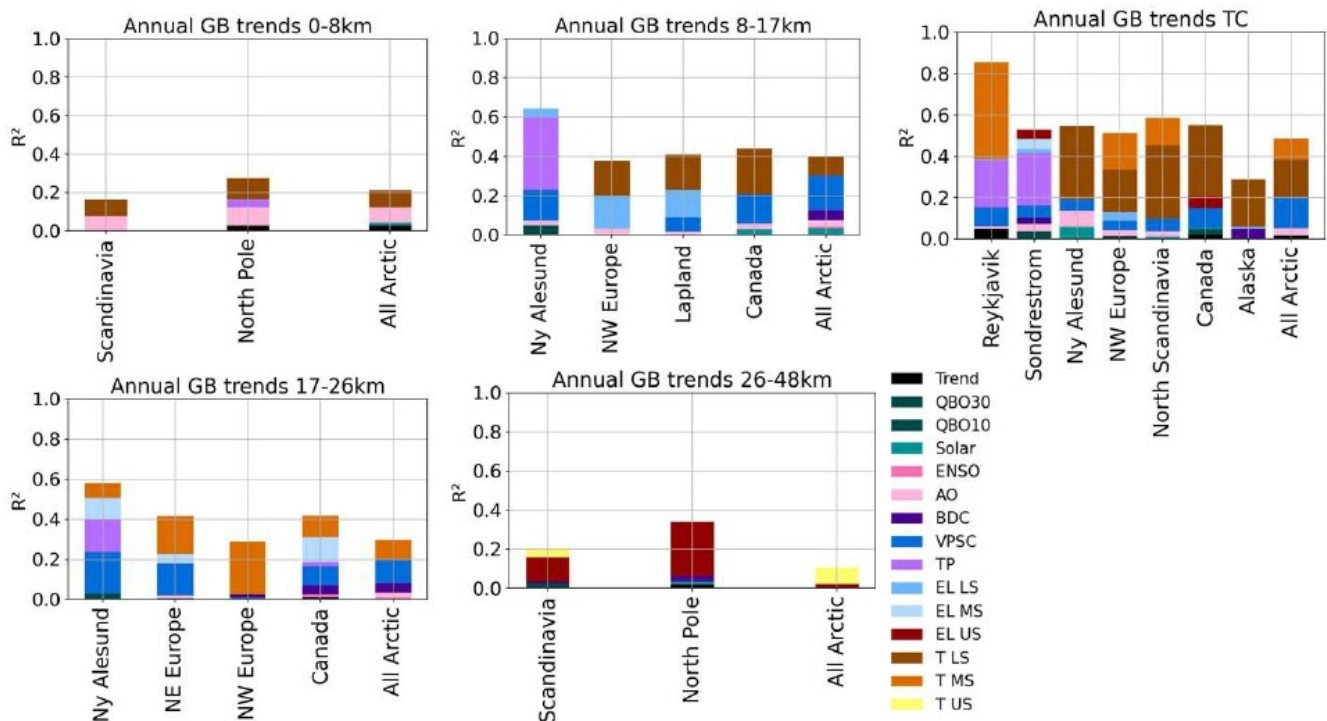

In the total column, we find that the variability is mostly explained by the lower and mid-stratospheric temperature ( $T_{LS}$  and  $T_{MS}$ ) and by the VPSC. As in partial columns, the AO, BDC, QBO, Solar cycle and equivalent latitudes account for smaller parts of the variability. The overall  $R^2$  values lay between 0.5 – 0.6, except in Reykjavik where it reaches beyond 0.8.

When analyzing contributing proxies to seasonal trends, shown in Fig. B1, we observe an overall homogeneity of proxies throughout regions, further strengthening the confidence in the results. The variability is in general best explained in Spring, with  $R^2$  values about 0.7 for the total column, reasonably well explained in Winter and Summer, and much less explained in Autumn, especially for merged groups of several stations. This is an interesting result, as the Arctic ozone loss due to ODS is expected to be the most important in Spring. The included proxies (such as VPSC which only occurs in Winter and Spring but also temperature and equivalent latitude) drives the better  $R^2$  values in Spring, Winter and Summer.

Finally, we have performed a sensitivity analysis to the VPSC proxy by running the trend analysis without including this proxy. We find that part of the variability explained by the VPSC is taken up by other proxies in its absence, in majority the BDC. This strong correlation between VPSC and BDC is well-known: a weak BDC is linked to lower temperatures and stronger vortex, and those conditions lead to more formation of PSCs (Langematz and Tully, 2018). Both VPSC (Rex et al., 2004) and BDC proxy (Weber et al., 2011) are linked to the same dynamical phenomena and correlate strongly with polar chemical ozone loss. The QBOs, AO, TP, EL and T contributions also increase to a lesser degree. In general, about half of the variability previously explained by the VPSC is not covered up by other proxies, resulting in a coefficient of determination  $R^2$  smaller by up to 0.3 in the lower and mid-stratosphere where the effect of VPSC is the strongest. Contrary to what was found in Bernet et al. (2023), we see that adding the VPSC proxy improves our model's fit in the total column.

### 5.3 Annual and seasonal trends

Before turning to the analysis of the trends results, it is important to stress that some of the proxies used in the MLR can themselves exhibit a trend. Whether or not these proxies trends should be part of the ozone trends depends on what we are trying to analyze. The VPSC for instance possesses a positive trend over the last two decades (von der Gathen et al., 2021; Pazmiño et al., 2023) due to climate forcing, which can be related to an increase of ozone depletion in the lower and mid-

**Figure 13.**  $R^2$  with individual contributions of proxies for all annual trends of ground-based instruments merged anomalies data sets for partial and total columns of ozone.

stratosphere. By including this proxy, together with its trend, in our MLR, we are effectively computing the ozone trend that is not due to this VPSC-related depletion. In the context of this study, this choice is justified by our aim in assessing the impact of the Montreal Protocol and its amendments, i.e., detecting the stratospheric ozone recovery associated with the diminution of ODS in the stratosphere. Therefore, our final trend results are calculated without detrending. We have nevertheless performed a sensitivity analysis by detrending each dynamical proxy (AO, BDC, VPSC, TP, EL, T) individually to assess their impact on the effective ozone levels and our conclusions. We compare trends obtained using the original proxy versus the detrended proxy, and we calculate the difference between the two. We find this difference is always non significant within the errors.

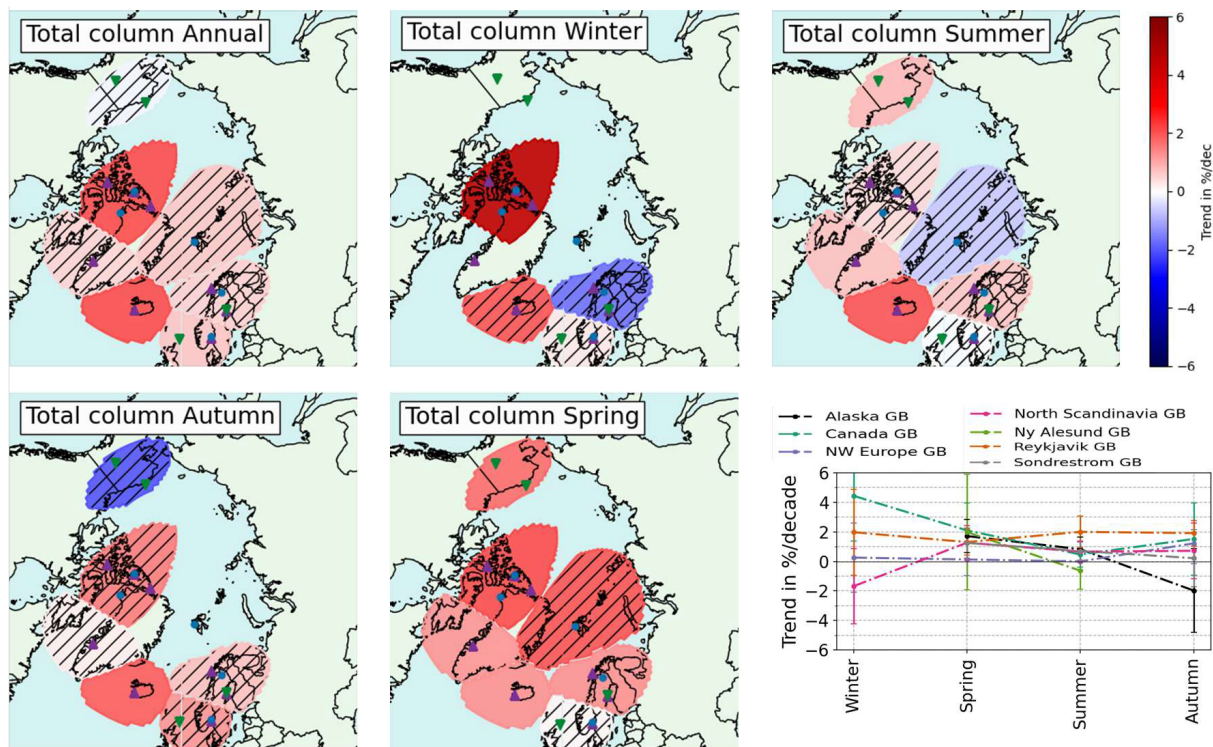

The mean absolute difference is of 0.80%/decade for VPSC detrending, 0.59%/decade for T detrending, 0.53%/decade for EL detrending, 0.35%/decade for AO detrending, 0.26%/decade for BDC detrending and 0.10%/decade for TP detrending. Although the differences are non-significant, the conclusions for very small trends such as in the lower stratosphere can be affected by those changes. First, the VPSC detrending always lowers trends, leading to non-significant negative trends in the lower and mid-stratosphere. The VPSC-Ozone recovery above Canada in the mid-stratosphere becomes non significant when the VPSC is detrended. Note that the VPSC correlation with ozone is always negative, confirming that the correlation relies on the interannual variability and not on the trend, as expected. In particular, the ozone recovery above Canada in the

540 ~~mid-stratosphere becomes non-significant when the VPSC is detrended. The temperature~~ Temperature detrending has a smaller effect but drives the lower stratosphere trends towards negative values and the mid-stratosphere ones towards positive values. This is expected since in the polar lower stratosphere, the stratospheric cooling enhances the formation of VPSC where most of ozone-depleting reactions occurs, while on the other hand, the stratospheric cooling in mid-stratospheric altitude is associated with a slowing down of reaction rates of homogeneous chemistry, inducing a negative correlation between ozone and  
545 temperature (Barnett et al., 1975; Haigh and Pyle, 1982). ~~The EL~~ detrending drives the trends in lower stratosphere, upper stratosphere and total column to slightly more positive trend values. ~~The AO~~ AO detrending also drives lower stratospheric trends to more negative values. Finally, TP detrending drives all individual stations trends to lower and more negative values. Since we defined layers using a fixed altitude boundary, the tropopause trend (Keppens et al., 2025) also affects tropospheric and lower stratospheric ozone trends. Detailed plots illustrating these trends comparisons are shown in Appendix in Figures  
550 C1, together with the trends obtained when including only the LOTUS proxies, i.e., Solar cycle, QBO and ENSO. The LOTUS trends are always smaller or more negative, because they do not include the VPSC, Temperatures and AO proxies. The uncertainties of the LOTUS trends are also always larger, making all LOTUS trends non-significant. Adding more proxies will always improve the  $R^2$  value, but it is non trivial that the uncertainty on the estimated trend is also improved, and this fact emphasizes the added value of our approach and of using more explanatory variables when calculating trends of a highly  
555 varying quantity such as ozone in the Arctic, and ensures that we are not overfitting our data.

We start by analyzing the total column trends results depicted in Figure 14. For this and all other columns, exact numbers with the associated  $2\sigma$  uncertainties, given both in %/decade and in DU/decade, are provided in the Appendix in Tables D1, D2 and D3. We have calculated annual trends which account for the full ozone anomalies time series, as well as seasonal trends divided in Winter (December-January-February), Spring (March-April-May), Summer (June-July-August) and Autumn  
560 (September-October-November). It is important to keep in mind that due to the polar night, Winter (and sometimes Autumn) trends only consist of sondes profile in partial columns and of less precise measurements for Dobson and Brewer in the total column, especially at the highest latitudes where the polar night extends from October to February. We only calculate trends for time series with more than a certain number of data points (80 for annual trends and 25 for seasonal trends), so some Winter or Autumn trends in the total column and upper stratosphere, where only FTIR are present, are not calculated. Fewer data points  
565 in Winter also implies that the variability is always larger for that season.

In the total column, trends are found to be overall positive. Except in Spring, there are some small negative trends but always non-significant. The trends in Canada, Reykjavik and Sondrestrom are always positive. The Lapland trend is negative only in Winter, the Alaska one only in Autumn and the Ny-Ålesund one only in Summer. Many positive trends are significant, especially in Spring, signalling the ozone recovery.

570 Previous studies of the total column of ozone in Arctic have found positive significant trends in individual stations. In Bernet et al. (2023), combined SAOZ, GUV and Brewer measurements led to annual positive significant trends at Andøya ( $0.9 \pm 0.7\%$ /decade) and Ny-Ålesund ( $1.5 \pm 1.0\%$ /decade), and a null trend at Oslo ( $0.1 \pm 0.5\%$ /decade) for the 2000 – 2020 period. Those values agree with our results within the  $2\sigma$  uncertainties. In Anjali and Kuttippurath (2025), Arctic **Zonal Band** total column trends based on merged SAOZ, GUV, Brewer and Dobson measurements on one hand and on merged TOMS and

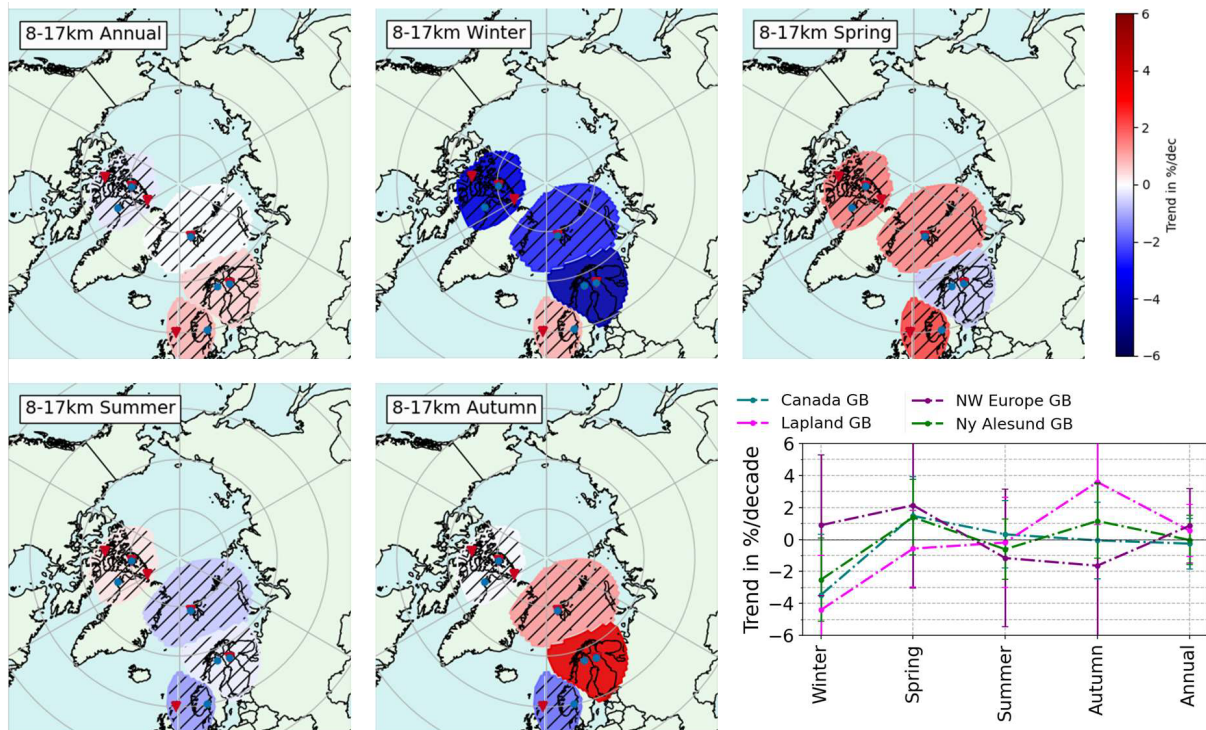

**Figure 14.** Annual and seasonal regional trends maps for the total column of ozone. Black hatches mean the trends are not significant. Exact trend values and their  $2\sigma$  uncertainties are displayed in the Appendix in Table D1.

575 OMI total column ozone (MSAT) data on the other hand, ~~are~~ were found positive and significant for the 2000 – 2024 period in Spring (~~resp.~~ respectively  $0.75 \pm 0.61$  and  $1.04 \pm 0.85$  DU/year), Autumn (~~resp.~~ respectively  $0.88 \pm 0.23$  and  $0.34 \pm 0.26$  DU/year) and annually (resp.  $0.65 \pm 0.39$  and  $0.85 \pm 0.60$  DU/year). In order to compare with literature, we calculated "~~zonal~~" Arctic zonal mean trends by merging all the Arctic ground-based stations used in this work for each partial and the total column ~~in a so-called~~ "Arctic-Zonal-Band". The results are provided in the Appendix in Table D1 and compare well with Anjali and Kuttippurath

580 (2025), although based on different instruments and methodology. Finally, we point out the significant negative ozone loss trends found in Pazmiño et al. (2023) for 2000 – 2021 when regressing ozone loss with ~~volume of polar stratospheric clouds~~ VPSC for the total column of ozone using chemical transport model TOMCAT/SLIMCAT, SAOZ ground-based instruments and Multi-Sensor Reanalysis (MSR2). Without the regression with VPSC, the ozone loss trend in Pazmiño et al. (2023) is not

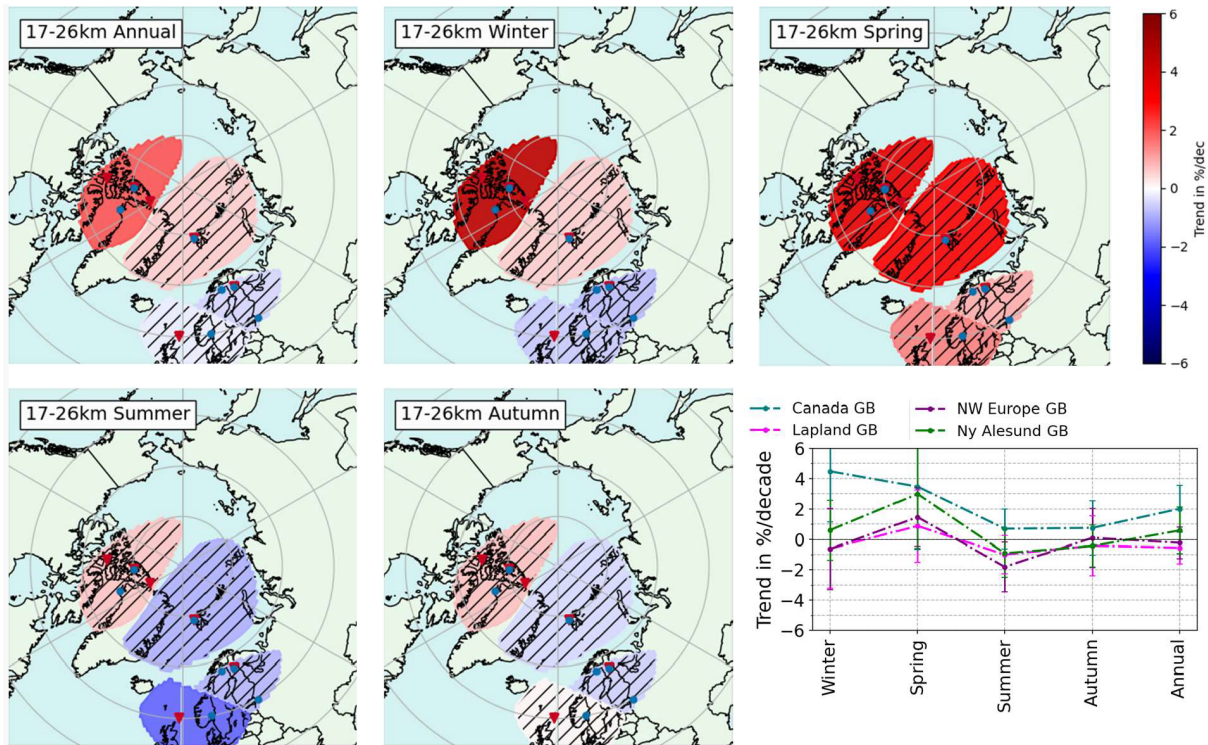

585 positive and significant ( $1.03 \pm 0.89\%$ /decade). However, our study is based on three additional years, which can accounts for the difference in significance.

We now review all partial column trends, starting with stratospheric columns. In the lower stratospheric column (8 – 17 km  $\sim$  300 – 100hPa), we find stronger seasonal and regional variations of the trends, see Figure 15. Most trends are non-significant,

**Figure 15.** Same as Figure 14 for the lower stratospheric column (8 – 17 km) ozone trends. Exact trend values and their  $2\sigma$  uncertainties are displayed in the Appendix in Table D2.

and they are all very small annually. They are usually strongly negative in Winter (even significantly for Lapland), and more positive in Spring. Lapland is however positive and significant in Autumn. Considering the seasonal pattern, the North-West Europe distinguishes itself from other regions with positive trends in Winter and negative trends in Autumn, although always non-significant. As shown in the Appendix in Figures C1, lower stratospheric trends become smaller or more negative when considering the detrended VPSC proxy. This means that the positive trend in VPSC in the Arctic is delaying the expected ozone recovery in the Arctic lower stratosphere. Trends in this layer in the Arctic are reported in Nilsen et al. (2024) for individual ozonesondes as well as in Millán et al. (2025) for two satellite data sets (ACE-FTS and MLS). The former uses Dynamical Linear Modelling (DLM) to obtain time-varying trends on 20-years periods, from 1994 – 2014 to 2003 – 2023. It considers 6 Arctic stations’ sondes data sets which are also used in the present work. We do not consider their Resolute and Scoresbysund results as we found spurious jumps for those data sets in section 3. At all remaining stations (Eureka, Alert, Ny-Ålesund and Sodankylä), they obtain negative annual trends within  $|1\%/decade|$  for their  $L_2$  (300 – 150hPa  $\sim$  8 – 13 km) and  $L_3$  (150 – 40hPa  $\sim$  13 – 22 km) layers for all periods after 1997 – 2017, with varying significance levels. These results are thus more negative than ours, although they agree within  $2\sigma$  errors. Besides our extended time-period and the addition of FTIR measurements, our analysis also differs in the proxies used for the regression. Nilsen et al. (2024) only considers the tropopause pressure, solar flux, Eddy heat flux (for the BDC) and the VPSC multiplied with Effective Equivalent Stratospheric Chlorine

**Figure 16.** Same as Figure 14 for the mid-stratospheric column (17 – 26 km) ozone trends. Exact trend values and their  $2\sigma$  uncertainties are displayed in the Appendix in Table D2.

(EESC), which measures the impact of ozone-depleting stratospheric chlorine and bromine levels in the Arctic stratosphere. We have not included the EESC here because we want our trend term to reflect the impact of the declining ODS levels. Moreover, we found the temperature and equivalent latitude proxies (not included in their study) play a very important role in explaining the variability at these altitudes. The second study (Millán et al., 2025) reports overall positive annual trends around 2%/decade for the MLS satellite in the 250 – 100hPa layer above 60°N. These trends are not significant using a simple linear regression but become larger, positive and significant when using MLR or DLM instead. The seasonal pattern matches with ours in Winter with large negative trends and in Spring with more positive trends. In Summer we obtain negative trends contrasting their positive trends and in Autumn, we observe a strong zonal difference not captured by the latitudinal band cut of the satellite. ACE-FTS trends are highly variable (sparser sampling) but also show positive trends using MLR and DLM between 200 – 100hPa in the 60 – 70°N latitudinal band.

In the ~~mid-stratosphere~~mid stratosphere, see Figure 16, we find positive trend values in Spring everywhere in the Arctic, while Canada trends are positive and significant in Winter and annually. There as well ~~the~~-VPSC detrending lowers trends (see Appendix Figures C1), highlighting that ozone recovery is delayed by this effect. In Sofieva et al. (2021), the annual trends at 20 km of altitude over the 2003 – 2018 period are very small on the whole region considered here, between –0.5

and +1%/decade, but not significant anywhere. Besides, our mid-stratospheric trends exhibit a consistent seasonal cycle, with highest (positive) ozone trends in Spring and lowest trends in Summer (significant negative in North-West Europe). The marked zonal asymmetry between Canada and Scandinavia is discussed below together with the upper stratosphere.

In the upper stratosphere (Figure 17), the annual trends above North Pole are positive and significant, consistent with the results of Sofieva et al. (2021) in the 25 – 30 km layer and supporting the detection of ozone recovery seen in the total column trends. Seasonal trends are always non-significant, therefore we have also considered additionally the 32 – 48 km layer. More positive trends are generally observed at higher altitudes as in Sofieva et al. (2021) at 40 and 45 km. Indeed we find larger positive significant trends at North Pole in Spring ( $6.06 \pm 4.19\%$ /decade) and annually ( $3.83 \pm 2.35\%$ /decade) for the 32 – 48 km layer.

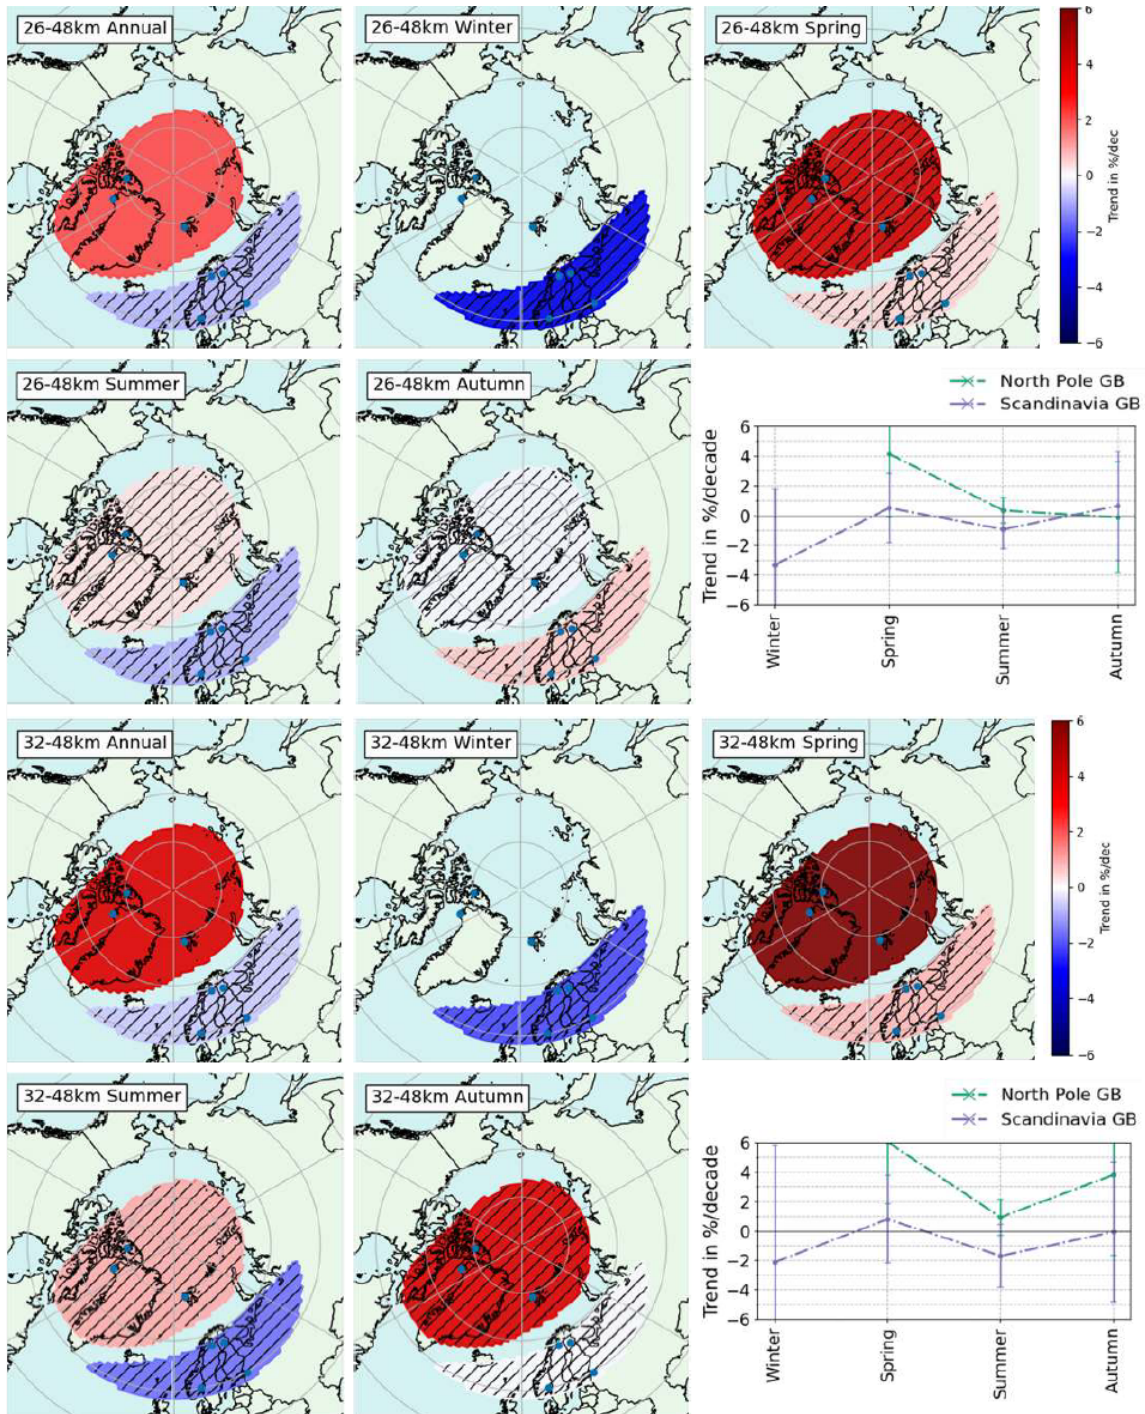

In middle and upper stratosphere, we ~~furthermore see a visible~~ observe a zonal asymmetry as ~~previously~~ detected by satellites and models (e.g. in Arosio et al., 2019; Sofieva et al., 2021), and attributed in Arosio et al. (2024) to decadal changes in the dynamics of the polar vortex above the Arctic, stemming from climate change forcing ~~in Arosio et al. (2024)~~. The zonal asymmetry is also visible when looking at which proxies are relevant: in the upper stratosphere, the North Pole trend is more influenced by the EL and the BDC, while the Scandinavian region is driven by the EL but to a lesser extent and slightly by temperature. Since the EL depends on the polar vortex, the zonal asymmetry is reduced by the use of that proxy, as it becomes larger in Spring when detrending the EL. Similarly in the mid-stratosphere, the Canada region is the only one where the BDC plays a significant role, especially important in Spring. This hints toward an explanation of the zonal asymmetry related to the atmospheric dynamics in the Arctic, in agreement with conclusions of ~~(Arosio et al., 2024)~~ Arosio et al. (2024).

Next we consider the tropospheric ozone column in Figure 18. We find that all tropospheric ozone trends are always negative in North Pole, significant both annually and in Spring, while Scandinavian trends are always non-significant, positive in Autumn and Winter and negative in Spring and Summer. In Van Malderen et al. (2025b), the HEGIFTOM measurements using homogenized sondes, FTIR, Lidar, Umkehr and IAGOS measurements lead to merged trend results on the 2000 – 2022 period for the tropospheric ozone column (surf.–300hPa) of  $(-1.80 \pm 0.37)$ ppb/decade in their European Arctic region and of  $(-1.09 \pm 0.57)$ ppb/decade in their Canadian Arctic region.<sup>1</sup> For a tropospheric column of 8 km, we can approximate  $1\text{DU} \sim 0.9\text{ppb}$  by integrating the air density column and assuming a linear decrease of temperature in the troposphere with altitude at a rate  $L = -0.0065\text{K/m}$ . This approximation will be sufficient in the context of this qualitative comparison. In North Pole (Canada+Ny-Ålesund), we find a negative but smaller annual trend of  $(-0.31 \pm 0.27)$ ppb/decade (see Table D2 for the equivalent DU/decade trends), at the limit of agreement with Van Malderen et al. (2025b) within mutual  $2\sigma$  errors. For Scandinavia we find much smaller non-significant annual trends of  $(-0.04 \pm 0.22)$ ppb/decade, not in agreement with the European Arctic value of Van Malderen et al. (2025b). The reasons for discrepancies are the exclusion of Scoresbysund, whose negative jump (see section 3.2) drives a fake negative trend when included, the addition of two years of data and the update of

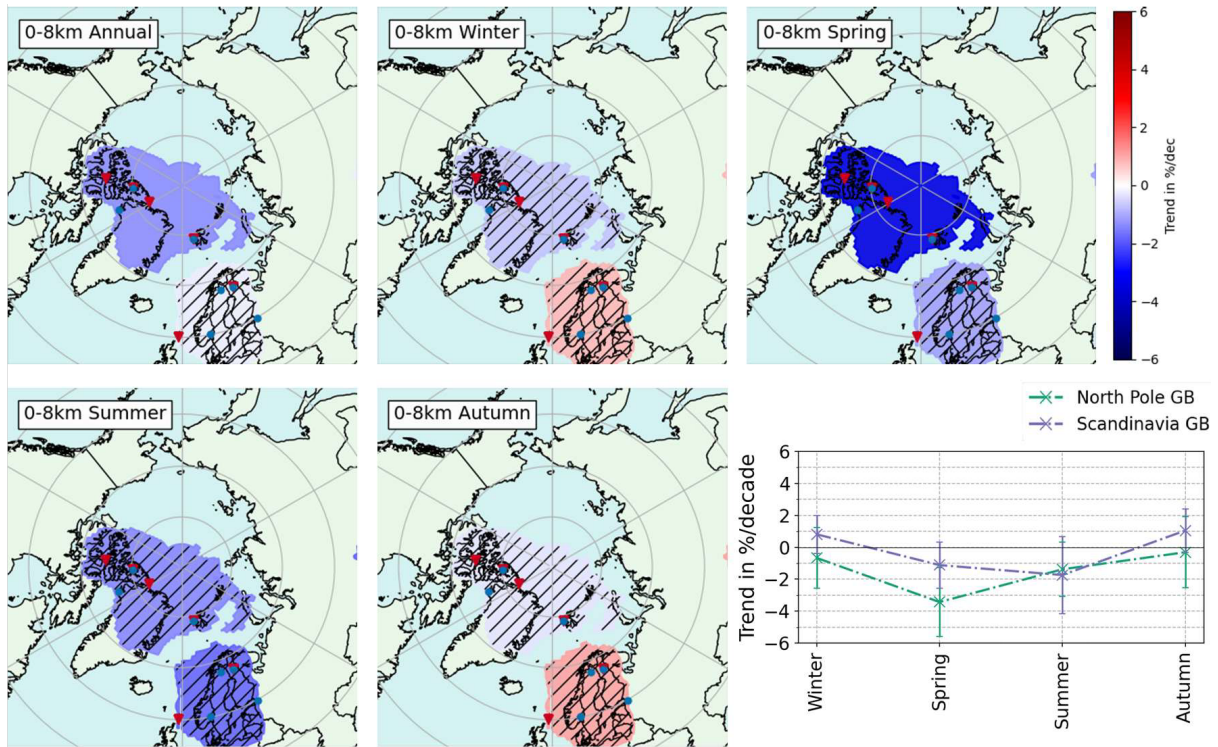

<sup>1</sup>Note that our regions differ from those of Van Malderen et al. (2025b) because we do not consider the Scoresbysund sonde where we found a spurious drift, and we have decided to include Ny-Ålesund together with Canadian sites instead of Scandinavian ones. The correlation of Ny-Ålesund with other sites is high everywhere (0.75 annually), but when we consider seasonal correlations, we find that it correlates better with Canada in Winter and Spring, and better with Scandinavia in Summer and Autumn. This is most probably an effect of the polar vortex displacement. We have chosen to include it with Canada based on the annual correlation values.

FTIR data sets to the new IRWG2023 strategy. ~~Our seasonal~~ Seasonal trends results in the troposphere exhibit a clear seasonal  
650 cycle, with more negative values in Spring and Summer and more positive or close to zero values in Autumn and Winter. A  
similar seasonal cycle was observed in Law et al. (2023) for the 1995 – 2019 period, using ground-based measurements and  
models, but with a shift (maximum in Summer). In that study, the increase in wintertime Arctic tropospheric ozone is linked  
to the reduction of NO<sub>x</sub> emissions in Europe and North-America mid latitudes, meaning less titration of ozone there, while  
the main source of tropospheric ozone at that time period comes from transports of air masses from mid to high latitudes. In  
655 the meantime, they relate the decrease in springtime tropospheric ozone to the reduction of European precursor emissions,  
implying less photochemical ozone production. Other factors such as the continued increase of methane or the increased dry  
deposition of ozone on boreal forest can also play a role.

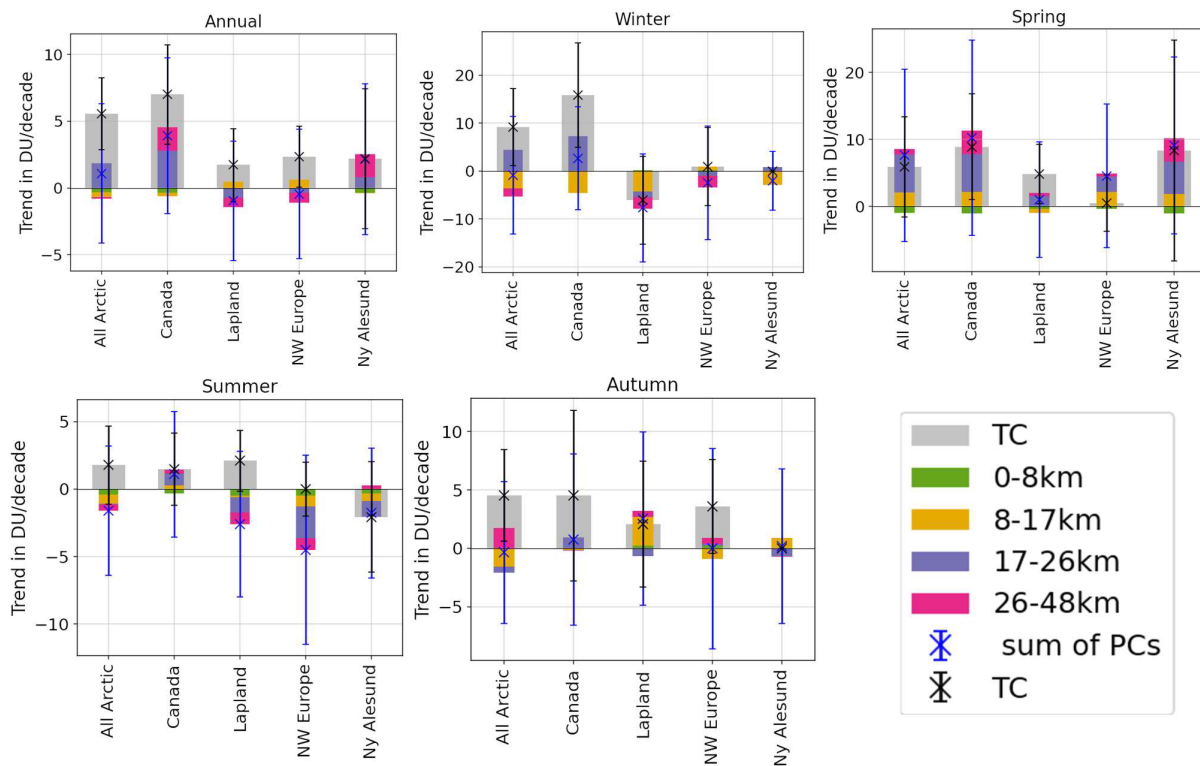

Finally, we can compare the total column trends to the sum of all partial column trends to see how they match with each  
other and what is the individual contribution of each partial column ~~trend~~ to the total ozone trend ~~,~~ (see Figure 19 for annual and  
660 seasonal trends). We sum partial column trends in DU/decade, obtained by multiplying the trends in %/decade by the mean  
total column value in the corresponding region. Since regions vary across partial columns, we consider equivalent regions  
that we have aligned vertically in Table 4 and that we name following the smallest represented regions (those of the lower  
stratosphere). They are: **Canada** (North Pole in troposphere and upper stratosphere), **Lapland** (North Scandinavia in total  
column, Scandinavia in troposphere and upper stratosphere, North-East Europe in mid stratosphere), **North-West Europe**  
665 (Scandinavia in troposphere and upper stratosphere) and **Ny-Ålesund** (North Pole in troposphere and upper stratosphere). In  
addition we also show the zonal ~~band~~-mean (All Arctic). ~~Our first conclusion is~~ We find that the impact of tropospheric trends  
is very small in DU/decade over the whole total column trend budget, ~~so the discrepancies observed between the total column  
and the stratospheric column trends cannot be explained by the negative tropospheric trends. We find overall agreement within  
the error bars of the total column trend and the sum of.~~ Within error bars, total column trends overall agree with respective  
670 sums of partial columns trends. This is a non trivial feature since the various columns use measurements from different sets  
of instruments. The best match of sums of partial column trends to total column trends is observed in Spring, comforting the  
results of ozone recovery at that season. In Ny-Ålesund in particular, the total column trend and the sum of partial columns  
trends agree very well both annually and for all seasons, although the upper stratospheric and total column trends are only  
given by the FTIR dataset while the three lower partial columns are a merging of the ozonesondes and FTIR data sets, see  
675 Table 2.

**Figure 17.** Same as Figure 14 for the upper stratospheric columns ozone trends. Exact trend values and their  $2\sigma$  uncertainties are displayed in the Appendix in Table D3.

**Figure 18.** Same as Figure 14 for the tropospheric ozone trends. Exact trend values and their  $2\sigma$  uncertainties are displayed in the Appendix in Table D2.

**Figure 19.** Sums of all partial column trends compared to total column trends in DU per decade for annual and seasonal trends. The groups are not always the same across the different layers, therefore we calculate sums for the smallest represented regions, i.e., the regions of the lower stratosphere (8-17 km). As shown in Table 4, we have for instance: Canada (TC) = North Pole (0-8 km) + **Canada (8-17 km)** + Canada (17-26 km) + North Pole (26-48 km) and North Scandinavia (TC) = Scandinavia (0-8 km) + **Lapland (8-17 km)** + North-East Europe (17-26 km) + Scandinavia (26-48 km).

## 6 Conclusions

By conducting a representativeness ~~analysis-study~~ based on CAMS re-analysis ozone profiles, we identified spatially coherent regions in which the combined time series yield reduced uncertainties and robust trend estimates for the total column as well as for four vertically resolved partial columns covering the troposphere and stratosphere (0 – 48 km), while enabling a finer  
680 description of ozone’s evolution than zonal bands.

Cross-comparison with IASI-CDR and MEGRIDOP ~~revealed-reveals~~ only minor drifts (< 3%/dec) in those satellite products stratospheric columns, consistent with satellite’s stability requirements (Weber, 2024), while it enabled us to exclude problematic ground-based data sets from our trend analysis. The tropospheric column of IASI is found to be slightly drifted beyond the stability requirement, so that continuous analysis is required to monitor the evolution of the drift.

685 Using a stepwise multiple-linear regression ~~;~~ incorporating nine physical proxies (solar cycle, QBO, ENSO, Arctic Oscillation, Brewer–Dobson circulation, equivalent latitude, stratospheric temperature, tropopause pressure and volume of polar stratospheric clouds) we are able to detect ozone recovery (over the 2000 – 2024 period) due to ODS depletion while attributing ozone’s variability to those physical processes. Despite the large amount of proxies used, the stepwise procedure ensures we are not overfitting, which is also verified through the improvement of fits and the reduction of trend uncertainties, visible  
690 e.g. when going from the LOTUS model to our full model. Moreover, the proxies analysis reveals a large consistency through regions, layers and seasons, giving us confidence in our trend results.

The obtained annual trends indicate a positive evolution of ozone total columns over the Arctic, statistically significant over Canada, Reykjavik (both +2.1%/dec), and North-West Europe (+0.7%/dec). We also detect an ozone recovery annually over the Canada region (+2%/dec) in the mid-stratosphere (17 – 26 km) and over the North Pole region (Canada + Ny-Ålesund)  
695 in the upper stratosphere (+2.1%/dec for 26 – 48 km and +3.8%/dec for 32 – 48 km). Those trends are more pronounced in Spring. Elsewhere and in the lower stratospheric column, trends are small and non-significant. Even when non significant, we see consistent seasonal patterns: e.g., trends are usually negative in Winter in the lower stratosphere (significantly for Lapland), and in Summer for the mid-stratosphere. The zonal asymmetry observed e.g., in Arosio et al. (2019); Sofieva et al. (2021) for the middle and upper stratosphere is ~~also-still~~ visible in our results, despite partially accounting for it through dynamical  
700 proxies.

By analyzing the proxies influences, we find that equivalent latitude, temperature and volume of polar stratospheric clouds dominate the variability budget in stratospheric columns. The tropopause pressure plays a significant role in explaining the variability for single-site regions. We also see a slow down of the expected ozone recovery especially in the lower stratosphere (but also regionally in upper layers) due to stratospheric cooling (-0.6%/decade) and the increase of volume of polar stratospheric  
705 clouds (-0.8%/decade).

Annual tropospheric ozone trends are negative in the North Pole region (Canada+Ny-Ålesund), but non-significant in Scandinavia. The tropospheric trends are more negative in Spring: -1.1%/dec in Scandinavia and -3.4%/dec (significant) in North Pole. The impact of the tropospheric trends is found to be negligible in the total column trend budget, as visible from the comparison of sums of partial columns versus total column trends.

710 Our study highlights the importance of long-term data sets of ozone measurements obtained simultaneously from a variety of ground-based instruments. Although ozone recovery starts to be observed in the Arctic, a continued monitoring is necessary to further assess the impact of climate change, which may undermine the efforts undertaken since the Montreal Protocol agreement, despite the successful reduction of ozone-depleting substances worldwide.
