Abstract

The China Meteorological Administration Global Forecast System (CMA-GFS) v4.0 model was upgraded to a higher resolution of 0.125° in May 2023. To be compatible with its fine resolution, the parameterization scheme of orographic gravity wave drag (OGWD) in CAM-GFS is revised herein by accounting for the nonhydrostatic effect (NHE) on the wave momentum flux of subgrid-scale orographic gravity waves. The performance of the revised OGWD scheme is then evaluated for the 10-day medium-range forecast in December 2023. Results show that the revised OGWD scheme can better capture the large-scale circulation in the Northern Hemisphere (NH), particularly in the high latitudes. The easterly (westerly) wind biases in the NH polar stratosphere (troposphere) are decreased. The underestimation of East Asia subtropical jet is also alleviated. Quantitative evaluation shows that the revised OGWD scheme reduces both the mean bias and root mean square error of 500-hPa geopotential height in the NH after the 6th forecast day, reaching 11.59% and 5.06%, respectively, by day 10. The decrease of easterly biases in the polar stratosphere is owing to the weakening of stratospheric zonal OGWD by the NHE. For the decrease of westerly biases in the NH polar troposphere, it is due to the fact that the enhanced stratospheric winds suppress the upward propagation of Rossby waves into the stratosphere, resulting in greater convergence of Eliassen-Palm flux in the mid-upper troposphere.

Keywords: orographic gravity wave drag, parameterization, global NWP medium-range forecast

1. Introduction

Orographic gravity wave drag (OGWD) is an important process in atmospheric dynamics, arising from the interaction of airflow with complex terrain (Kim et al., 2003; Teixeira, 2014). When airstream flows over mountains, it generates orographic gravity waves (OGWs) which propagate vertically. As these waves break, they transfer momentum from the surface to higher levels (Fritts and Alexander, 2003). This momentum transfer plays a crucial role in driving the atmospheric circulation, influencing both tropospheric and stratospheric dynamics (Alexander et al., 2010).

In numerical weather prediction (NWP) and climate models, the OGWD is typically a subgrid-scale process which needs to be parameterized. Various OGWD parameterization schemes have been developed over the past few decades (e.g., Palmer et al., 1986; McFarlane, 1987; Kim and Arakawa, 1995; Lott and Miller, 1997; Scinocca and McFarlane, 2000; Kim and Doyle, 2005) based on both linear and nonlinear OGW dynamics. Their implementation has been shown to help alleviate the systematic biases in both NWP and climate models, ranging from general circulation to regional climate and weather (e.g., Kim, 2007; McLandress et al., 2012; Choi and Hong, 2015; Zhong and Chen, 2015; Chen et al., 2016; Lu et al., 2020; Zhang et al., 2020; Li et al., 2023; Xu et al., 2023; Wei et al., 2025).

While accurate representation of OGWD is essential for weather forecast and climate simulation/projection, traditional OGWD parameterization schemes rely on the assumption of hydrostatic balance which can significantly simplify the formulae of OGW dynamics. This assumption is appropriate for coarse-resolution numerical models where subgrid-scale OGWs are dominated by hydrostatic GWs as the dominant subgrid

68 "mountains" are large. However, as the model resolution increases, the hydrostatic
69 assumption becomes less valid because the subgrid-scale orography (SSO) becomes
70 smaller, so that the unresolved GWs have shorter wavelengths. In this situation, the
71 nonhydrostatic effects (NHEs) will exert remarkable influences on the subgrid-scale
72 OGWs. Compared with hydrostatic OGWs, nonhydrostatic OGWs experience stronger
73 horizontal dispersion of wave energy, which reduces wave amplitude and can suppress
74 wave breaking and momentum deposition into the mean flow (Smith, 1979; Klemp and
75 Durran, 1983; Zängl, 2003). These NHEs are thus critical for accurately representing
76 the dynamical impacts of subgrid-scale OGWs in high-resolution models, e.g., the
77 *state-of-the-art* global NWP models.

78 Recently, Xu et al. (2021) theoretically derived the analytical expressions for
79 the surface wave momentum flux (WMF) of nonhydrostatic OGWs generated by
80 idealized three-dimensional orography. They found that the degree of nonhydrostaticity
81 can be measured by a nondimensional parameter of Froude number which is equal to
82 the wind speed over the mountain half width and buoyancy frequency, i.e., the inverse
83 of the nondimensional half-width Na/U (e.g., Zängl, 2003). Physically, this parameter
84 represents the ratio between the period of buoyancy oscillation and the time for airflow
85 travelling through the mountain. The larger the horizontal Froude number, the more
86 important the NHE is. Based upon the theoretical study, Xu et al. (2023, 2024) revised
87 the OGWD parameterization scheme developed by Kim and Doyle (2005, hereafter
88 KD05) by accounting for the NHE on the surface WMF of upward-propagating OGWs.
89 Then the new OGWD scheme was implemented in the Model for Prediction Across
90 Scales (MPAS), which was shown to improve the seasonal simulation of the

stratospheric polar night jet and reduce the wet biases over the western Tibetan Plateau in winter. Li et al. (2024) further evaluated the revised OGWD scheme in the Weather Research and Forecasting (WRF) model for short-range forecast of Northeast China cold vortices (NECVs). The underestimation of the NECV intensity (in terms of minimum 500-hPa geopotential height) is alleviated as the NHE decreases the lower-tropospheric OGWD.

The China Meteorological Administration Global Forecast System (CMA-GFS) is a rename of the Global/Regional Assimilation and Prediction System (GRAPES) developed in early 2000s (Shen et al., 2017). Operationally running at the CMA Earth System Modeling and Prediction Center, the CMA-GFS was upgraded to a new version of v4.0 in May 2023, with its horizontal resolution increasing from about 0.25° to 0.125° (about 13 km), along with many other improvements in the model dynamics and physics (Shen et al., 2023). For instance, the convective triggering function and quasi-equilibrium closure conditions are improved to reduce biases in tropics and enhance forecast skill of precipitation in East Asia. In CMA-GFS, three components of subgrid scale orography effects have been implemented, i.e., the blocking-flow drag (BFD), the OGWD and turbulent orographic form drag (TOFD). The TOFD scheme was implemented CMA-GFS based on Beljaars et al. (2004) and Xue et al. (2011) and will not be further discussed as it is not relevant to the NHE effect studied in this study. The BFD component based on Lott and Millor (1997, hereafter LM97) and OGWD component from Kim and Arakawa (1995, hereafter KA95) were implemented in CMA-GFS similar to that in Alpert (2004) and was described in Chen et al. (2016). It is noticed that in the existing implementation, nonhydrostatic effects are only partly reflected

114 through a Scorer-parameter-based partitioning of the momentum stress when the model
115 grid point is located downstream of the subgrid orography. However, the launch-level
116 surface WMF itself still follows the original hydrostatic KA95 formulation. In order to be
117 compatible with its high resolution, this hydrostatic OGWD parameterization scheme
118 needs to be upgraded to account for the NHE.

119 Note that the present study extends the evaluation of the nonhydrostatic OGWD
120 scheme in the MPAS model presented in Xu et al. (2024) by transitioning it into a
121 practical, operational NWP. Although Xu et al. (2024) demonstrated the beneficial
122 impact of the revised OGWD scheme for long-term, large-scale circulation simulations,
123 its performance and value within a state-of-the-art, high-resolution global forecasting
124 system performing routine medium-range forecasts had not been tested. This work
125 provides this critical assessment using the CMA-GFS v4.0 model, with a specific focus
126 on forecast skill improvements for several quantitative metrics. The primary advance
127 lies in evaluating the revised OGWD scheme in reducing systematic forecast biases on
128 timescales directly relevant to weather prediction (1-10 days). Therefore, this research
129 bridges the gap between parameterization development and operational implementation,
130 demonstrating the tangible benefits of incorporating nonhydrostatic effects to improve
131 medium-range weather forecasting accuracy.

132 The remainder of the paper is organized as follows. Section 2 firstly introduces
133 the revision of the OGWD parameterization scheme and then describes the setup of the
134 numerical experiments. Section 3 gives an overall evaluation for the medium-range
135 forecast of large-scale atmospheric circulation by the CMA-GFS model. The NHE

136 effects on parameterized OGWD and large-scale circulation are examined in section 4.
137 Finally, the paper is summarized in section 5 along with discussions.
138
139 **2. OGWD parameterization scheme and numerical experiments**
140 a. Revision of the KA95 OGWD parameterization scheme
141 The KA95 OGWD considers various aspects of the SSO including its standard
142 deviation (σ_h), orographic asymmetry (OA) and orographic convexity (OC). The
143 surface WMF of OGWs is given by

144 $$\tau_0 = \rho_0 E \frac{m}{\lambda_{eff}} G \frac{|V_0|^3}{N_0}, \quad (1)$$

145 where

146 $$E = (OA+2)^{C_E \frac{Fr_0}{Fr_c}}, m = (1+L_x)^{OA+1}, G = \frac{Fr_0^2}{Fr_0^2 + C_G OC^{-1}}, Fr_0 = \frac{\sigma_h N_L}{|\mathbf{V}_L|}. \quad (2)$$

147 The variables ρ_0, $|\boldsymbol{V_0}|$ and N_0 are the low-level (from the surface to $2\sigma_h$) mean air
148 density, horizontal wind speed and buoyancy frequency. The parameter m denotes the
149 "number of mountains" within the grid cell, characterizing the total volume of SSO
150 associated with the orography length (L_x). The coefficient λ_{eff} acts as a tunable
151 parameter denoting the effective grid length. The transition function G is an
152 enhancement factor for sharp mountains as OC is large. This scheme also considers the
153 effects of low-level wave breaking and/or lee wave trapping through the factor E, which
154 is a function of the shape and location of the SSO within the model grid cell (i.e., OA),
155 and the flow nonlinearity (i.e., $Fr_0 = \frac{Nh_0}{U}$). The two empirical constants are set to C_E =
156 0.8 and C_G = 0.5, which are obtained empirically through a series of numerical
157 simulations conducted in Kim and Arakawa (1995).

158 The surface WMF is transported upward level by level until reaching the model
159 top or critical level. At each model level, airflow instability is checked according to the
160 hypothesis of wave saturation (Lindzen, 1981) and wave-breaking (Miller and Palmer,
161 1986).

162 Once the subgrid-scale OGWs saturate and break, they will exert a body force
163 on the mean flow through the deposition of wave momentum, namely,

164 $$\frac{d\boldsymbol{V}(z)}{dt} = \frac{1}{\rho(z)}\frac{\partial \boldsymbol{\tau}(z)}{\partial z}. \quad (3)$$

165 where $\boldsymbol{V}(z)$ and $\boldsymbol{\tau}(z)$ are the mean flow velocity and the WMF at height z, respectively.
166 Note that both the directions of $\boldsymbol{V}(z)$ and $\boldsymbol{\tau}(z)$ are parallel to the mean flow at the low
167 level (i.e., $\boldsymbol{V_L}$). Readers are referred to KA95 for more details about the scheme.

168 The hydrostatic KA95 scheme above is revised by taking into account the NHE
169 on the surface WMF of OGWs, i.e.,

170 $$\tilde{\tau} = \tau_0[1 + NHE(Fr)]. \quad (4)$$

171 $\tilde{\tau}$ represents the nonhydrostatic surface WMF, where the NHE correction depends only
172 on the horizontal Froude number $Fr = \frac{|\boldsymbol{V_0}|}{N_0 L_x}$

173 $$NHE(Fr) = -\frac{9}{8}Fr^2 + e^{-2Fr^{-1}}\left(-\frac{5}{4}Fr^{-2} - \frac{1}{2}Fr^{-1} + \frac{5}{4} + \frac{9}{4}Fr + \frac{9}{8}Fr^2\right). \quad (5)$$

174 Eq. (5) is adopted from Xu et al. (2021) for three-dimensional isotropic terrain. Specifically,
175 the nonhydrostatic correction is defined as the ratio of the analytically derived
176 nonhydrostatic surface WMF to its hydrostatic counterpart, which yields an algebraic
177 correction factor depending only on the horizontal Froude number. Note that the
178 horizontal Froude number is different from the traditional Froude number Fr_0 above
179 which measures the flow nonlinearity. While Xu et al. (2021) have derived the fully

NHE for anisotropic terrain, the expressions involve complicated integrals that are not suitable for practical use in parameterization [cf. their Eqs. (14) to (17)]. Xu et al. (2021) demonstrated that terrain anisotropy only has a very weak influence on the NHE, so the expression of NHE for isotropic terrain, i.e., Eq. (5), is used because of simplicity, since only algebraic manipulations are involved. This is in agreement with Xu et al. (2023, 2024) and Li et al. (2024).

b. Setup of numerical experiments

The CMA-GFSv4.0 dynamical core is based upon the nonhydrostatic and shallow atmospheric governing equations in spherical polar coordinates with full physics packages (Shen et al., 2020). It adopts a regular latitude-longitude grid of 0.125°× 0.125° with *C*-grid staggering. In the vertical, a terrain-following height-based grid is utilized along with Charney-Phillips staggering. There are 87 vertical levels, with the model top located at 73 km. For model physics, the Liu-Ma microphysics scheme (Ma et al., 2018) is employed, along with the RRTMG longwave and shortwave radiation schemes (Morcrette et al., 2008), the MRF planetary boundary layer scheme (Chen et al. 2020; Hong and Pan 1996), the CoLM land surface model (Dai et al., 2003), NSAS convection scheme (Han and Pan, 2011; Liu et al., 2015), the combined KA95 OGWD and LM97 FBD parameterization scheme (Chen et al., 2016), and modified Beljaars's TOFD scheme (Xue et al., 2011).

In order to examine the impact of the revised OGWD scheme on the medium-range forecast, two sets of numerical simulations (i.e., EXP_CTL and EXP_NHE) are conducted with different OGWD parameterization schemes, using the original KA95

scheme and the revised nonhydrostatic one, respectively. Both experiments consist of 31 individual forecasts, each initialized at 00 UTC for the days from 1 to 31 December 2023. Herein, a winter month is chosen because the OGWD, which is mainly located in the Northern Hemisphere (NH) given the pronounced orography, is the strongest in this season (e.g., Xu et al. 2020; Lu et al. 2024). In each experiment, the CMA-GFS model is integrated for 10 days, i.e., medium-range forecast, with 6-hr output interval. The model initial conditions are derived from the 0.25° × 0.25° ECMWF Reanalysis v5 (ERA5) dataset (Hersbach et al., 2020), which are also used as reference for the evaluation of the CMA-GFS forecasts. Although the horizontal resolution of ERA5 is coarser than that of the CMA-GFS v4.0 simulations, ERA5 is adopted here as the verification reference because it is a dynamically consistent reanalysis constrained by a broad range of assimilated observations. In this study, ERA5 is not used to resolve the non-hydrostatic subgrid-scale orographic gravity waves themselves. Instead, it serves as a benchmark for evaluating the large-scale circulation response and medium-range forecast skill associated with the revised OGWD parameterization.

3. Evaluation of the medium-range forecast

a. Atmospheric circulation

Figure 1 shows the zonal-mean zonal wind composited from the day 10 forecast output of the 31 simulations initialized at 00 UTC on 1-31 December 2023. Accordingly, the valid times of these day-10 forecasts span 10 December 2023 to 10 January 2024 (i.e., the 10th day of the medium-range forecast). In the winter of NH, as revealed by the ERA5 reanalysis (Fig. 1a), there is a subtropical jet in the midlatitudes troposphere and

226 stratosphere, with the jet core located at about 200 hPa and 30°N. The maximum zonal
227 wind speed exceeds 35 m s^{-1}. In the stratosphere of high latitudes, there is another wind
228 maxima near 1 hPa and 60°N, which is the well-known polar-night jet (e.g., Kim, 2007)..
229 In the Southern Hemisphere (SH), which is in summer, there is also a upper tropospheric
230 lower stratospheric jet but relatively weaker and lower than in the NH. The SH jet core
231 is located at about 50°S, with a secondary one near 30°S. During austral summer, the
232 SH stratosphere is dominated by easterlies, which is distinctly different from the NH. With
233 a center located near 1 hPa and 20°S, the stratospheric easterlies extend downward and
234 equatorward to the tropics. An easterly jet of over -30 m s^{-1} can be found near 20 hPa
235 and 5°S.

236 Figure 1b is similar to Figure 1a but for the zonal-mean zonal winds obtained in
237 the EXP_CTL experiment. In general, the CMA-GFS model can capture the overall
238 pattern of the zonal-mean zonal winds, such as the tropospheric westerly jets in both
239 hemispheres and the easterly winds in the SH stratosphere. The polar night jet in the
240 NH, however, is underestimated by the model, with the jet core shifted southward by
241 about 10 latitudes. As shown in Fig. 1c, there are notable easterly biases of over -5 m
242 s^{-1} in the stratosphere of the NH high latitudes (north of 50°N). By contrast, westerly
243 biases are present in the upper stratosphere of the NH midlatitudes (25°N-50°N) which
244 can exceed 10 m s^{-1}, extending downward and equatorward to the lower stratosphere of
245 the tropics. Similarly, the zonal-mean zonal winds in the NH troposphere are
246 overestimated in the Arctic region, but with easterly biases in the mid-lower latitudes.
247 In the SH, the stratospheric easterlies are shifted northward, leading to westerly biases
248 in the mid-lower latitudes (40°S-5°S) and easterly biases in the tropics and lower

249 latitudes of the NH (5°S-20°N). In the high latitudes, there are predominantly easterly
250 biases in both troposphere and stratosphere except in the upper stratosphere over the
251 polar cap.

252 When taking into account the NHE in the OGWD parameterization scheme, the
253 CMA-GFS model can better capture the large-scale circulation. Figure 1d presents the
254 differences between the zonal-mean zonal winds in the two numerical experiments (i.e.,
255 EXP_NHE minus EXP_CTL). In the stratosphere above ~10 hPa, positive and negative
256 wind differences are found to the north and south of 60°N, respectively, which are just
257 opposed to the wind biases in Figure 1c. It suggests that both the magnitude and location
258 of the polar night jet are improved. For example, the NH easterly biases in the mid-
259 upper stratosphere (~10 hPa to 1 hPa) are reduced by about 3%. The westerly biases in
260 the troposphere of Arctica region are also reduced, which reaches up to about 42% of
261 the total bias. At the same time, the easterly wind biases in the mid-latitude troposphere
262 have also reduced.

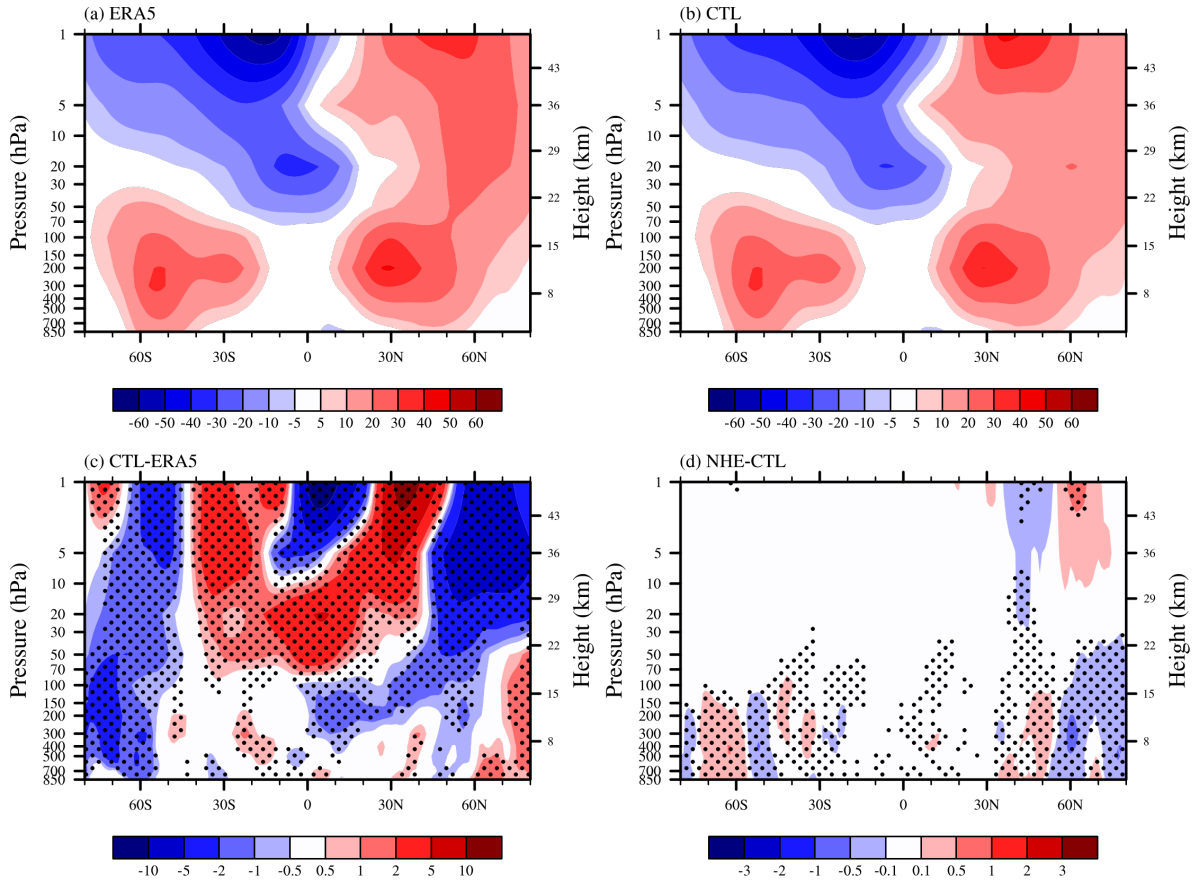

Figure 1. Vertical distributions of zonal-mean zonal wind (units: m s^{-1}) averaged in the period of 10 December 2023 to 10 January 2024 obtained from (a) ERA5 and (b) EXP_CTL, with their difference (i.e., EXP_CTL minus ERA5) given in (c). (d) is similar to (c) but for the difference between the two experiments of EXP_NHE and EXP_CTL (i.e., EXP_NHE minus EXP_CTL). Stippling in (c) and (d) denote differences statistically significant at the 95% confidence level.

For the zonal-mean zonal wind biases in the SH stratosphere, they are hardly alleviated, however. This is because the stratospheric OGWD is very weak in summer (see Fig. 5a of Xu et al. 2024; see also Fig. 3 below), given the absorption of OGWs at the critical level (Booker and Bretherton, 1967), that is, the zero-wind level between the tropospheric westerlies and the stratospheric easterlies (Fig. 1a). The easterly biases in the troposphere of the high latitudes are reduced, especially around 60°S.

Although there is no significant improvement for the zonal-mean zonal wind in the NH mid-lower latitudes (Fig. 1d), the wind circulation can be improved regionally, such as the East Asia subtropical jet (EASJ). Figure 2a shows the horizontal wind field and speed at 200 hPa averaged in the period of 10 December 2023 to 10 January 2024 from the ERA5 reanalysis. In boreal winter, the EASJ stretches from about 110°E to 160°E in the latitudes between about 25°N and 45°N. The jet core is located near Japan, showing a high wind speed of over 70 m s^{-1}. The simulated EASJ in the EXP_CTL experiment generally aligns well with the ERA5 reanalysis, in terms of its location and orientation (Fig. 2b). But the jet intensity is underestimated, showing easterly biases of over -4 m s^{-1} (Fig. 2c). In the EXP_NHE experiment, the underestimation of the EASJ is alleviated, with the mean bias decreased by about 6% (Fig. 2d).

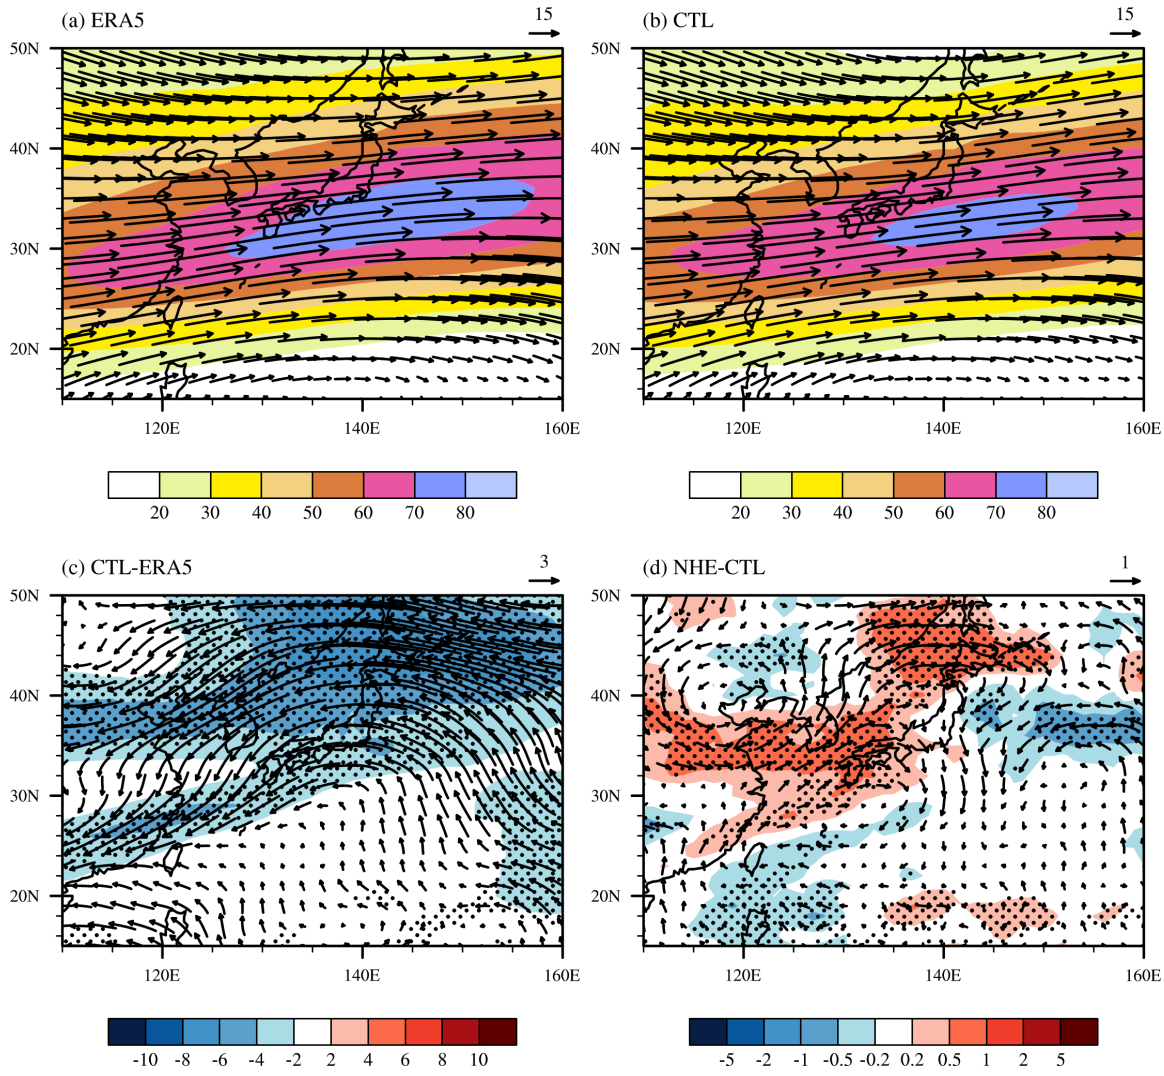

Figure 2. Horizontal distributions of wind speed (shading; units: m s^{-1}) and wind filed (arrow) at 200 hPa averaged in the period of 10 December 2023 to 10 January 2024 obtained from (a) ERA5 and (b) EXP_CTL, with their difference (i.e., EXP_CTL minus ERA5) given in (c). (d) is similar to (c) but for the difference between the two experiments of EXP_NHE and EXP_CTL (i.e., EXP_NHE minus EXP_CTL). Stippling in (c) and (d) denote differences statistically significant at the 95% confidence level.

b. Quantitative evaluation of forecast skills

For medium-range forecast, the wind circulation in the troposphere is often of greater interest than in the stratosphere. To better evaluate the performance of the revised OGWD scheme, Figures 3a and 3b depict the mean bias (MB) and root mean square error (RMSE) for the 500 hPa geopotential height (GPH500) in the two experiments. Herein, we are interested in the NH because of the relatively weak wind differences in the SH (Fig. 1d) which is mainly covered by the ocean. Moreover, as will be shown below, the parameterized OGWD changes little in the SH.

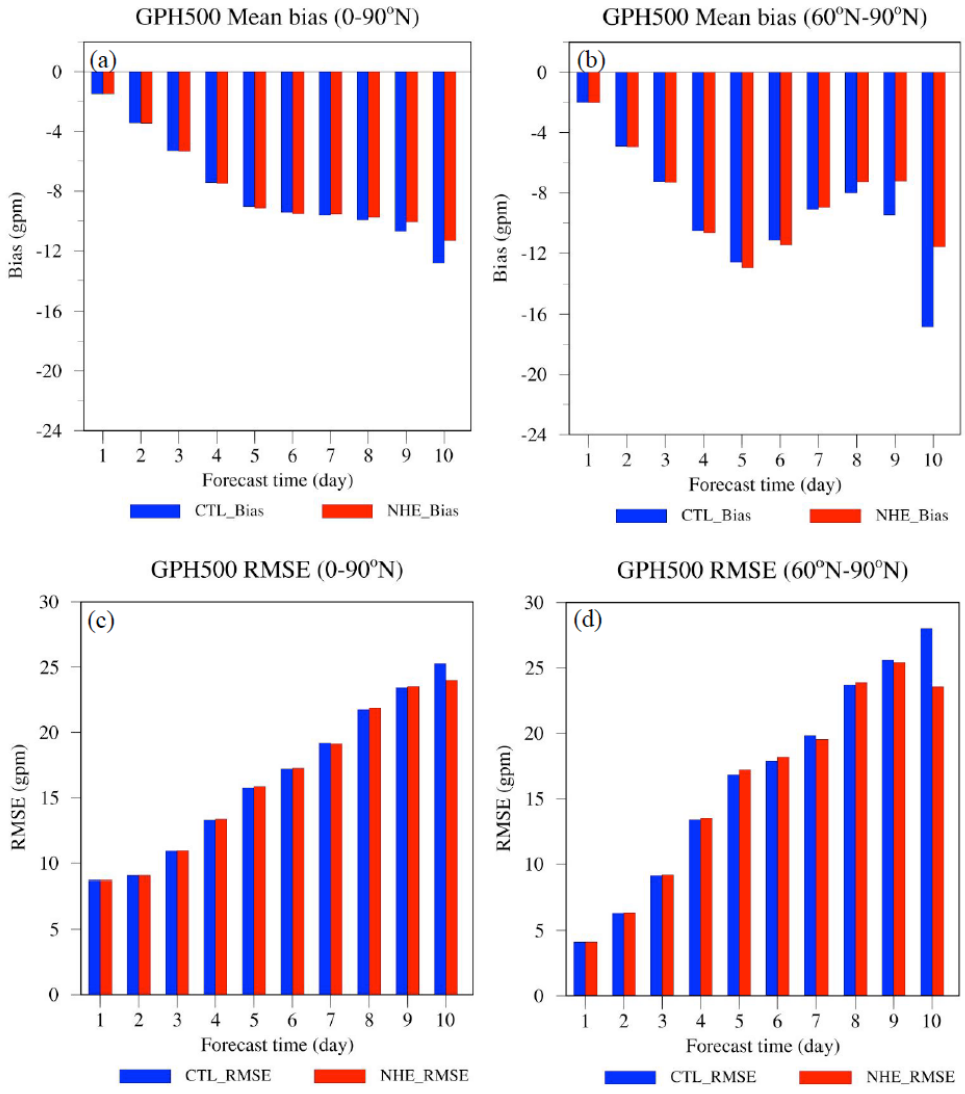

Figure 3. (a) Mean bias and (c) RMSE of the GPH500 in the NH at different forecast lead time. (b) and (d) are similar to (a) and (c) but in the region north of 60°N.

In both experiments, the model GPH500 is lower than the ERA5 reanalysis, with the MB and RMSE increasing with the forecast lead time (Figs. 3a, 3c). The GPH500 shows obvious underestimation in the EXP_CTL experiment which are significantly reduced in EXP_NHE. This improvement is particularly evident in high latitudes north of 60°N which is overall statistically significant at the 95% confidence level (Figs. 4a, 4b). Compared to EXP_CTL, EXP_NHE exhibits even greater MB and RMSE of GPH500 till the 6th forecast day. Nevertheless, both the MB and RMSE of the GPH500 decrease quickly afterwards, which are reduced by 11.59% and 5.06%, respectively, at the 10th day of the forecast (Table 1). Greater improvements are found for the GPH500 between 60°N and 90°N, the MB and RMSE of which are decreased by 31.18% and 15.93%, respectively, at the 10th forecast day (Table 1). All the values shown in Table 1 are statistically significant at the 95% confidence level. For the total 10 forecast days as a whole, the MB and RMSE of GPH500 are separately reduced by 2.6% and 0.52 %, indicating an overall improvement in the simulation of the large-scale circulation in the NH when using the revised OGWD scheme (see Table 2).

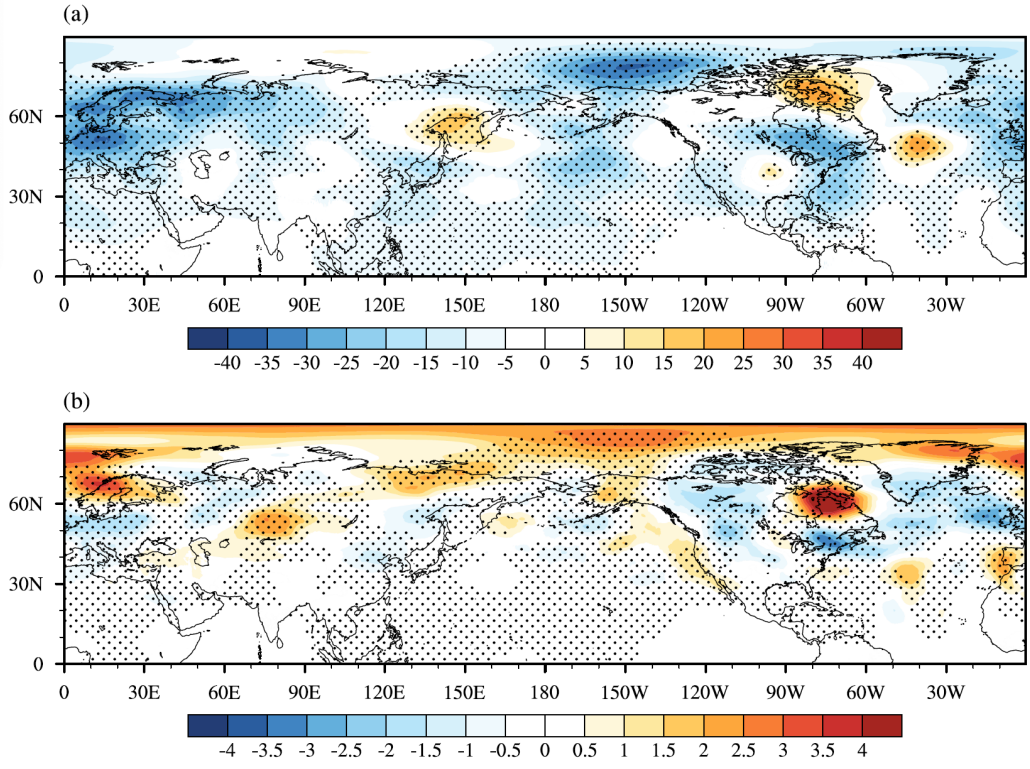

Figure 4. (a) Mean biases of GPH500 (shading; units: gpm) in EXP_CTL experiment as compared to ERA5 averaged over the ten forecast days. (b) is similar to (a) but for the differences between the GPH500 (shading; units: gpm) in EXP_CTL and EXP_NHE experiments (i.e., EXP_NHE minus EXP_CTL). Stippling in (a) and (b) denote differences statistically significant at the 95% confidence level.

Table 1. Mean bias and RMSE of the 500-hPa geopotential height (GPH500) and sea level pressure (SLP) at the 10th forecast day

		Mean Bias			RMSE		
	Region	CTL	NHE	$\frac{\text{NHE}-\text{CTL}}{CTL}\times 100$	CTL	NHE	$\frac{\text{NHE}-\text{CTL}}{CTL}\times 100$
GPH500 (gpm)	0-90°N	-12.825	-11.338	-11.59	25.263	23.984	-5.06
	60°N-90°N	-16.841	-11.590	-31.18	28.017	23.554	-15.93
SLP (hPa)	0-90°N	-0.522	-0.343	-34.29	2.714	2.515	-8.33
	60°N-90°N	-1.712	-1.079	-36.97	3.049	2.517	-17.45

Table 2. Mean bias and RMSE of the 500-hPa geopotential height (GPH500) and sea level pressure (SLP) for the overall ten forecast days

		Mean Bias			RMSE		
	Region	CTL	NHE	$\frac{\text{NHE}-\text{CTL}}{CTL}\times 100$	CTL	NHE	$\frac{\text{NHE}-\text{CTL}}{CTL}\times 100$
GPH500 (gpm)	0-90°N	-7.923	-7.717	-2.6	16.455	16.369	-0.52
	60°N-90°N	-9.187	-8.438	-8.15	16.470	16.089	-2.31
SLP (hPa)	0-90°N	-0.107	-0.082	-23.46	1.87	1.841	-1.53
	60°N-90°N	-0.498	-0.411	-17.47	1.598	1.532	-4.13

Besides the GPH500, the forecast skill is also examined for the SLP in the NH. As shown in Fig. 5a, the EXP_CTL experiment systematically underestimates the SLP over East Asia and the Arctic, while overestimating SLP across North America and the northern Atlantic. These biases are substantially corrected in the EXP_NHE experiment, particularly in high-latitude regions north of 60°N (Fig. 5b). Similarly, the EXP_NHE experiment firstly experiences a degradation in the early 6 days compared to EXP_CTL, but it shows significant improvement at the end of the 10th forecast day, with the MB reduced by 34.29% and the RMSE by 8.33%, respectively (Table 1). Greater decreases of 36.97% (for MB) and 17.45% (for RMSE) are found in the high latitudes north of 60°N as well.

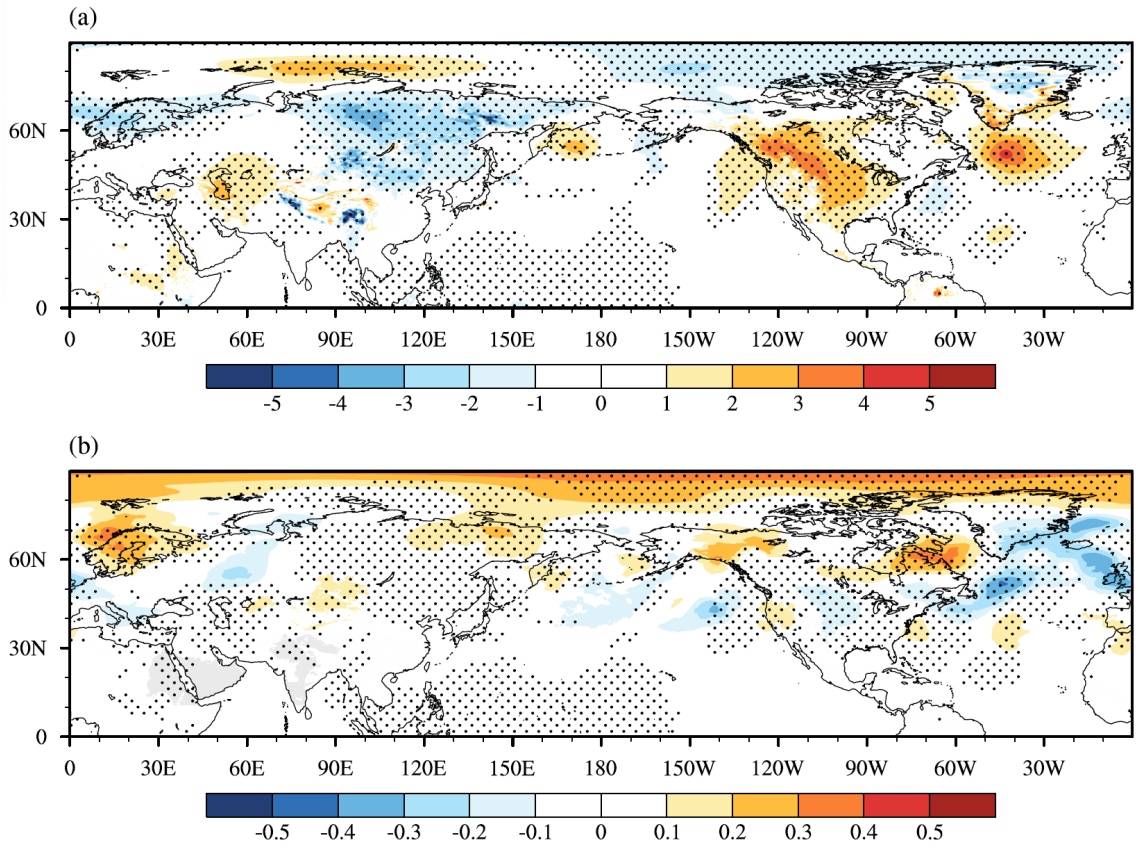

Figure 5. (a) Mean biases of SLP (shading; units: hPa) in the EXP_CTL experiment as compared to ERA5 averaged over the ten forecast days. (b) is similar to (a) but for the differences between the SLP (shading; units: hPa) in the EXP_CTL and EXP_NHE experiments (i.e., EXP_NHE minus EXP_CTL). Stippling in (a) and (b) denote differences statistically significant at the 95% confidence level.

From the above analyses, implementing the revised OGWD scheme in the high-resolution CMA-GFS model can help improve the medium range forecast of the NH large-scale circulation, especially in the high latitudes. In the next section, we will examine the underlying mechanisms responsible for the improvement of the circulation.

4. Physical interpretation

a. Changes of parameterized OGWD

The changes of wind circulation arise from the revision of the OGWD scheme. It is thus straightforward to study the parameterized OGWD in these two experiments. Figure 6a shows the vertical distribution of zonal-mean zonal OGWD averaged in the period of 10 December 2023 to 10 January 2024 in the EXP_CTL experiment. The differences between the parameterized OGWD in the two experiments (i.e., EXP_NHE minus EXP_CTL) are given in Fig. 6b. In boreal winter, there exists prominent OGWD in the stratosphere of the NH mid-to-high latitudes, which is favored by the decrease of air density with height (e.g., Lindzen, 1981) and the relatively weak winds between the tropospheric jet and polar night jet. The latter is called as the "valve layer" by Kruse et al. (2016). The maximum OGWD occurs between about 20 hPa and 1 hPa. In contrast, there is very weak OGWD in the SH stratosphere owing to the critical level absorption as mentioned above.

Compared to that in EXP_CTL, the zonal-mean zonal OGWD in EXP_NHE is generally weakened in the high latitudes of the NH (north of about 55°N), especially in the stratosphere (Fig. 6b). Note that the positive difference indicates a decrease of OGWD as the drag itself is negative. This is due to the fact that the NHE acts to decrease the surface WMF [see Eqs. (4) and (5)], i.e., the source of parameterized OGWs which determines the maximum wave momentum that can be deposited into the mean flow. Therefore, the decrease of surface WMF is prone to reduce the OGWD. Note that there is also enhancement of OGWD, e.g., in the stratosphere near 50°N. This may be attributed to a decrease in surface WMF, which suppresses tropospheric wave breaking

by lowering the gravity-wave amplitude limit for breaking at lower levels and thus shifts the wave-breaking altitude upward. Consequently, a vertical structure characterized by alternating positive-negative-positive anomalies from the surface to the stratosphere would be expected. In consequence, more WMF is transported to the stratosphere where the OGWs break owing to the decay of air density and lead to stronger OGWD. This is similar to the redistribution of WMF in the vertical owing to selective critical level filtering of OGWs in directional shear flows (Shutts, 1995; Xu et al., 2012, 2019; van Niekerk et al., 2023). Generally, the changes in the vertical structure of parameterized OGWD in the CMA-GFS model are similar to that in the MPAS seasonal simulations conducted in Xu et al. (2024) which also considers the NHE correction to the OGWD (cf. their Fig. 5).

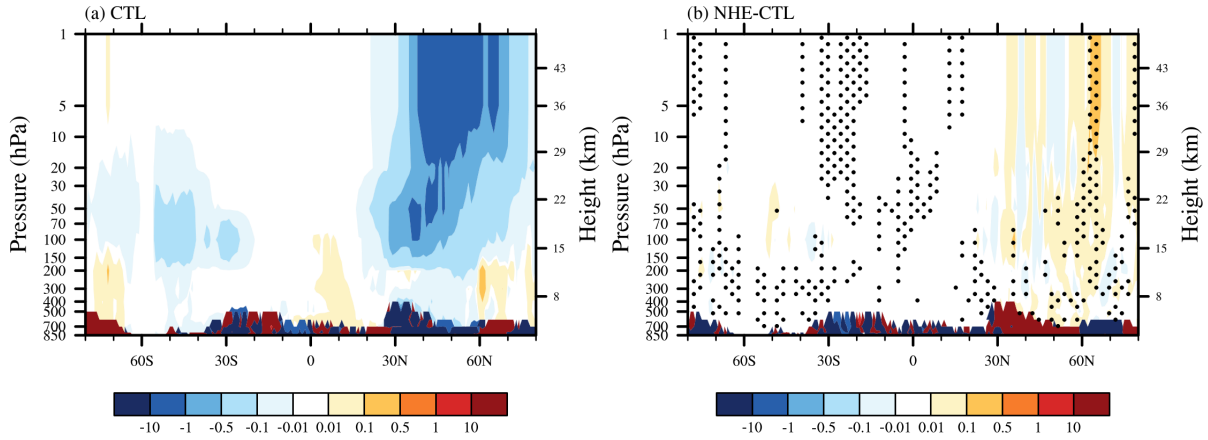

Figure 6. Vertical distributions of (a) zonal-mean zonal OGWD (units: m s^{-1} day^{-1}) averaged in the period of 10 December 2023 to 10 January 2024 obtained from EXP_CTL, and (b) zonal-mean OGWD difference between the two experiments of EXP_NHE and EXP_CTL (i.e., EXP_NHE minus EXP_CTL). Stippling in (b) denotes differences statistically significant at the 95% confidence level.

The weakening of OGWD can directly increase the zonal winds in the polar stratosphere and the mid-latitude troposphere of the NH, thus leading to a recover of the weakened westerly jet. Conversely, the enhancement of OGWD can directly weaken the zonal winds in the mid-latitude stratosphere and the polar troposphere of the NH, thereby reducing the westerly biases (Figs. 1c, 1d). The parameterized OGWD in East Asia is also examined to explain the changes of EASJ. As shown in Fig. 7a, there is notable westward OGWD at 200 hPa in the high latitudes of East Asia where the underlying terrain is very complex, such as the Taihang, Yanshan, Changbai, Greater Khingan and Lesser Khingan Mountains. Thus, the largest easterly biases of the EASJ occur in this region (Fig. 2c). When accounting for the NHE in the OGWD parameterization scheme, the 200-hPa OGWD is mainly reduced (Fig. 7b). Clearly, the enhanced EASJ is owing to the weakening of the parameterized OGWD.

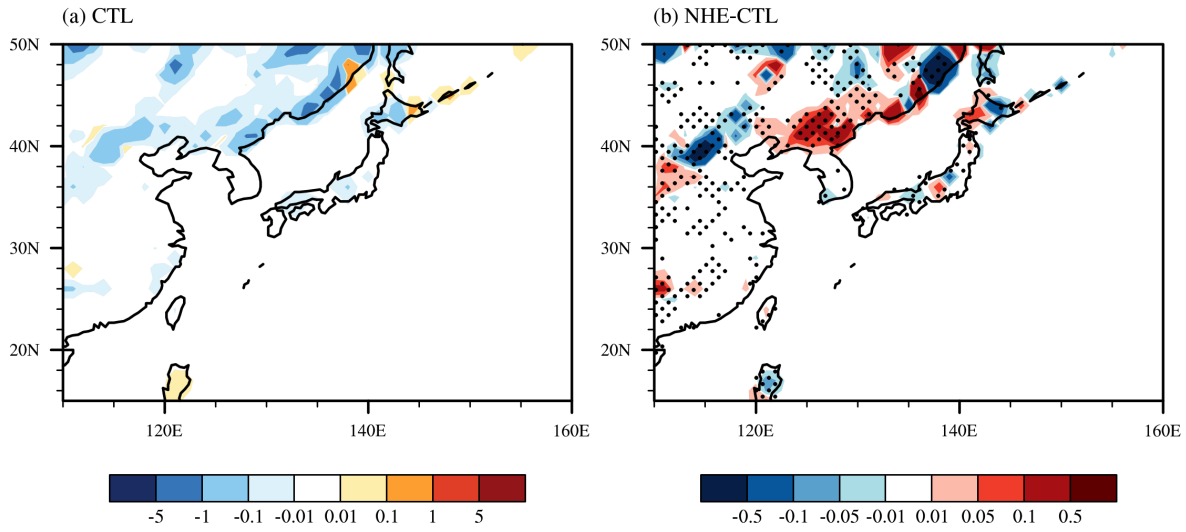

Figure 7. Horizontal distributions of (a) zonal OGWD (units: m s^{-1} day^{-1}) at 200 hPa averaged in the period of 10 December 2023 to 10 January 2024 obtained from EXP_CTL, and (b) zonal OGWD difference between the two experiments of EXP_NHE

and EXP_CTL (i.e., EXP_NHE minus EXP_CTL) at 200 hPa. Stippling in (b) denotes differences statistically significant at the 95% confidence level.

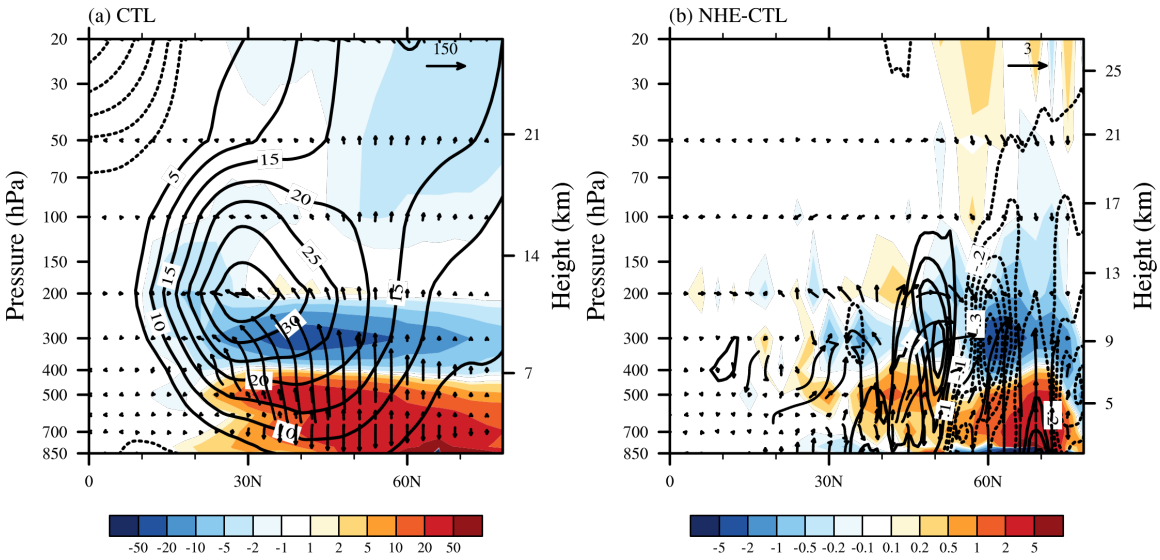
b. Resolved Rossby-wave adjustment

In addition to the direct effect of the modified OGWD, the tropospheric response in the Northern Hemisphere is also associated with an adjustment of resolved large-scale Rossby waves. This interpretation is consistent with the wave-drag compensation and propagation-adjustment mechanisms discussed in previous studies (e.g., Cohen et al., 2013; Sigmond and Shepherd, 2014). In particular, changes in the background zonal wind may alter the propagation conditions for planetary waves and thereby redistribute the resolved wave forcing between the troposphere and stratosphere.

It is well known that the impacts of large-scale Rossby waves on the mean flow can be measured by the convergence of the zonal-mean Eliassen-Palm (EP) flux. Figure 8a illustrates the distribution of the zonal-mean EP flux in the EXP_CTL experiment which is calculated following Edmon et al. (1980). In the NH middle-to-high latitudes, Rossby waves originate from the lower troposphere which propagate upward and converge in the upper troposphere. These waves split into two branches in the lower stratosphere. The first branch turns to propagate equatorward across the tropospheric jet. The other branch continues to propagate upward to the upper stratosphere where the EP flux is converged and decelerates the mean flow. As in the SH, the Rossby waves cannot propagate into the stratosphere (not shown) because of the presence of easterlies there during austral summer (Fig. 1a).

Figure 8b is similar to Fig. 8a but gives the differences between the zonal-mean EP fluxes in the two experiments (i.e., EXP_NHE minus EXP_CTL). Compared to

448 EXP_CTL, the upward propagation of Rossby waves into the stratosphere is suppressed
449 in the high latitudes of the NH, leading to an enhanced convergence of EP flux in the
450 troposphere. As a result, the zonal-mean zonal winds in the NH polar troposphere are
451 decelerated by the large-scale Rossby wave forcing, which contributes to the alleviation
452 of westerly biases there (Figs. 1c, 1d). This may explain why the improvements in the
453 GPH 500 forecast emerge after 6 days in EXP_NHE (Fig. 2). The Rossby waves and
454 their interaction with the mean flow require several days to develop fully and influence
455 the large-scale circulation.
456



457

458 Figure 8. Vertical distributions of zonal-mean EP flux (vectors) and its divergence
459 (shading; m s^{-1} day^{-1}) due to resolved waves averaged in the period of 10 December
460 2023 to 10 January 2024 obtained from (a) EXP_CTL, and (b) the difference between
461 the two experiments of EXP_NHE and EXP_CTL (i.e., EXP_NHE minus EXP_CTL).
462 Contours are the corresponding zonal-mean zonal wind (units: m s^{-1}).
463

The suppressed upward propagation of Rossby waves can be understood from the changes of the refractive index (*RFI*) that measures the ability of Rossby wave propagation (e.g., Chen and Robinson, 1992; Hu et al., 2019), which is defined as

$$RFI = \left[\frac{\overline{q_\varphi}}{r\bar{U}} - \left(\frac{k}{rcos\varphi}\right)^2 - \left(\frac{f}{2NH}\right)^2\right] r^2 , \quad (6)$$

where $\bar{U}$, k and H are the resolved zonal-mean zonal wind, zonal wave number and density scale height, respectively. $\overline{q_\varphi}$ represents the meridional gradient of the potential vorticity, which is expressed in the following form of

$$\overline{q_\varphi} = 2\Omega\cos\varphi - \left[\frac{(\bar{U}cos\varphi)_\varphi}{acos\varphi}\right]_\varphi + \frac{af^2}{R_d}\left(\frac{p\theta}{T}\frac{\overline{U_p}}{\overline{\theta_p}}\right)_p . \quad (7)$$

where Ω, θ and R_d being the Earth's angular frequency, potential temperature and dry gas constant, respectively. The subscripts φ and p represent the partial derivatives with respect to latitude and pressure, respectively. The overbars indicate temporal and zonal averages. From Eq. (6), the increase of zonal wind will narrow the range of Rossby wave numbers that can propagate into the stratosphere (Charney and Drazin, 1961; Xu et al., 2024).

As shown in Fig. 9, positive *RFI* values for both zonal wavenumbers 1 and 2 are found over the northern mid- to high latitudes in EXP_CTL, indicating that the basic-state flow is favorable for the upward propagation of planetary waves (Figs. 9a, 9c). In EXP_NHE, however, the *RFI* is generally reduced over the same region, especially in the upper troposphere and lower stratosphere. These negative *RFI* anomalies suggest that the strengthened background westerlies in the polar stratosphere make the

484 environment less conducive to the vertical propagation of Rossby waves (Figs. 9b, 9d).
485 Similar behavior is found for both wavenumber-1 and wavenumber-2 components,
486 although the wavenumber-1 signal appears more spatially coherent. Therefore, the
487 reduction of *RFI* provides a dynamical explanation for the weakened upward EP-flux
488 branch seen in Fig. 8b.

489 Physically, the revised OGWD scheme weakens the parameterized drag in the
490 northern polar stratosphere, which strengthens the local westerlies. Stronger
491 background westerlies narrow the range of planetary-wave numbers that can propagate
492 vertically into the stratosphere. Consequently, the upward propagation of resolved
493 Rossby waves is suppressed, and less resolved wave forcing reaches the polar
494 stratosphere. This effect acts together with the weakened parameterized OGWD to
495 reduce the easterly wind bias in the polar stratosphere. At the same time, the associated
496 redistribution of resolved wave forcing favors a weakening of the polar-tropospheric
497 westerlies, thereby contributing to the improvement of the large-scale circulation over
498 the northern high latitudes.

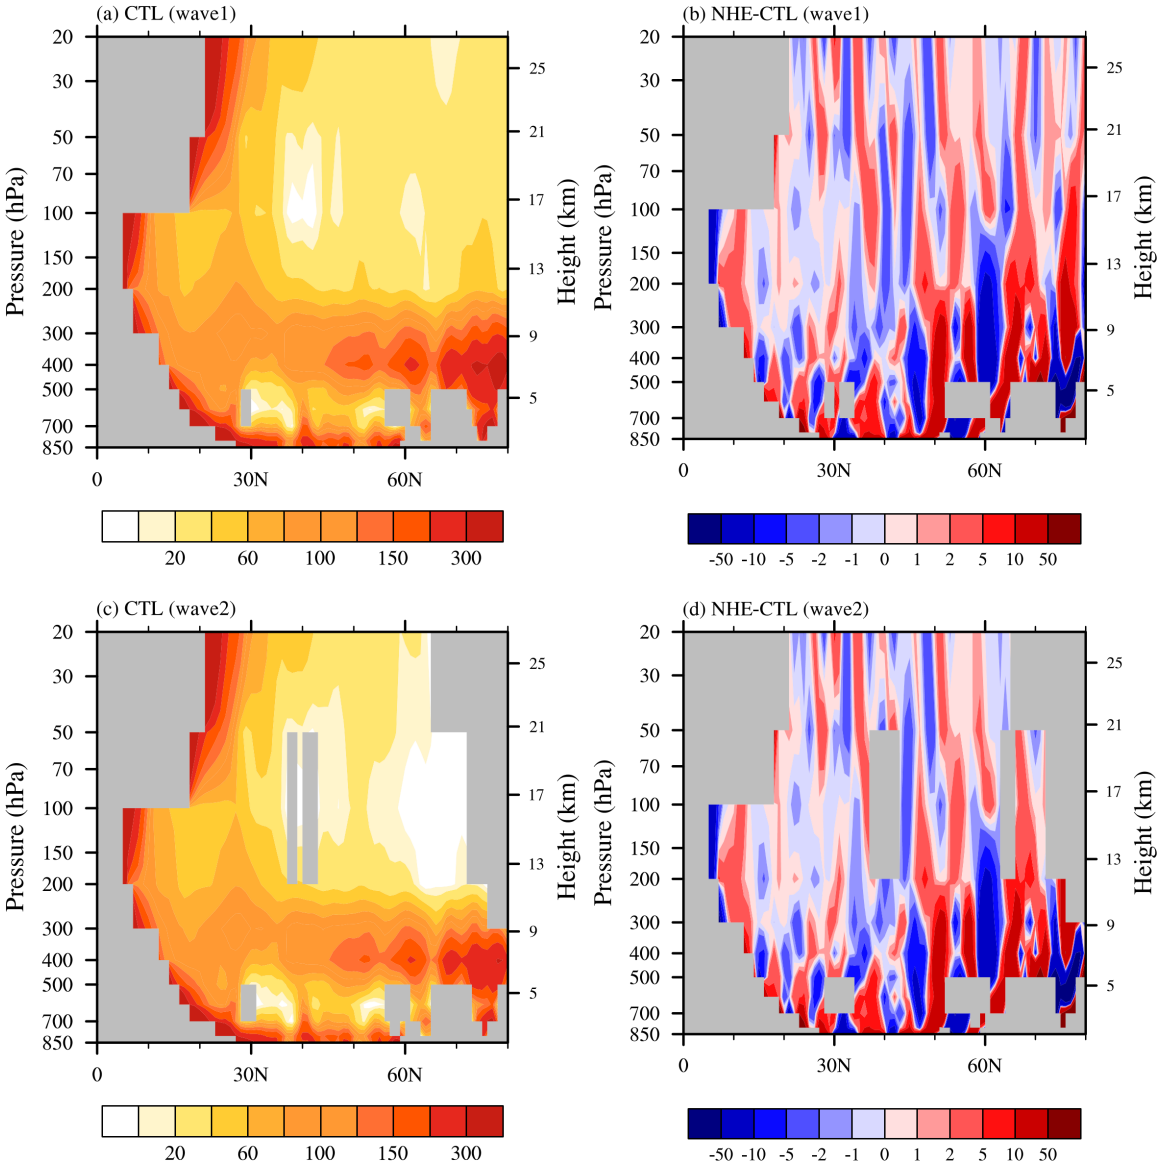


Figure 9. Refractive index for the (a) wavenumber-1 and (c) wavenumber-2 resolved waves averaged over the period of 10 December 2023 to 10 January 2024 in the EXP_CTL experiment. (b) The difference between the refractive indices of wavenumber 1 in EXP_NHE and EXP_CTL (EXP_NHE minus EXP_CTL). (d) As in (b), but for wavenumber 2.

4. Summary and discussions

The latest China Meteorological Administration Global Forecast System (CMA-GFS) v4.0 model has been upgraded to a higher resolution of 0.125° in 2023. However, this high-resolution global model still uses the parameterization scheme of orographic gravity wave drag (OGWD) developed by Kim and Arakawa (1995; KA95) which is based on hydrostatic orographic gravity wave (OGW) theory. In this study, the KA95 OGWD scheme is revised by taking into account the nonhydrostatic effect (NHE) on the surface wave momentum flux (WMF) of OGWs, according to the nonhydrostatic OGW theory derived in our earlier study of Xu et al. (2021). The performance of the revised OGWD scheme is then evaluated for the medium-range forecast of the CMA-GFSv4.0 model. Two sets of numerical experiments (i.e., EXP_CTL and EXP_NHE) are conducted by using the original KA95 scheme and the revised NHE scheme, respectively. In each numerical experiment, there are in total 31 forecasts of 10-day forecasts. In each numerical experiment, there are in total 31 independent 10-day forecasts which are initiated at 00 UTC on each day of December 2023.

The results show that the revised OGWD scheme can improve the medium-range forecast of large-scale circulation in the Northern Hemisphere (NH), especially in the high latitudes. The easterly biases of zonal-mean zonal wind in the NH stratosphere are reduced, with both the magnitude and location of the polar night jet being better captured. The underestimation of the East Asia subtropical jet (EASJ) is also alleviated. In contrast, the revised OGWD scheme shows little influence on the stratospheric circulation in the Southern Hemisphere (SH). This is because, in boreal winter (i.e., austral summer), there is hardly OGWD in the SH stratosphere owing to the effect of critical-level absorption, leading to comparatively smaller circulation

responses. Therefore, the quantitative evaluation of forecast skill is mainly performed for the NH, where the impact of the revised OGWD scheme is physically more pronounced and statistically more robust.

Quantitative evaluation is performed for the medium-range forecast skills in the NH, taking the ERA5 reanalysis dataset as reference. Both experiments showed lower geopotential height (GPH) at 500 hPa than ERA5 reanalysis, with the mean bias (MB) and root mean square error (RMSE) increasing with forecast lead time. EXP_NHE initially has greater MB and RMSE than EXP_CTL until the 6th forecast day, but these metrics decrease more rapidly afterwards, resulting in an 11.59% reduction in MB and a 5.06% reduction in RMSE by day 10. Over the total 10 forecast days, the MB and RMSE of the GPH 500 in the NH are reduced by 2.6% and 0.52%, respectively, indicating improved simulation of large-scale circulation in the NH. The improvement is more noticeable in the high latitudes north of about 60°N, where the MB and RMSE of GPH 500 are decreased by 31.18% and 15.93% at the 10th forecast day. Similar results are found for the sea level pressure (SLP) in the NH, the MB and RMSE of which are reduced by 34.29% and 8.33%, respectively, by day 10 in EXP_NHE.

The dynamics responsible for the improvement of large-scale wind circulation are examined. The NHEs act to decrease the surface WMF of OGWs, which leads to a general weakening of the parameterized OGWD in the midlatitudes and high latitudes of the NH. This weakening of OGWD directly increases the zonal winds in the mid-latitude troposphere and polar stratosphere, reducing the easterly biases. The enhanced zonal wind in the polar stratosphere acts to narrow the range of large-scale Rossby wave numbers that can propagate into the stratosphere by reducing the refractive index of Rossby waves.

553 The suppressed upward propagation of Rossby waves leads to greater convergence of
554 Eliassen-Palm (EP) flux (i.e., resolved wave forcing) in the NH polar troposphere, which
555 decelerates the zonal winds and thus alleviates the westerly biases there.

556 To sum up, this study demonstrates that incorporating the NHE into the OGWD
557 parameterization scheme can help improve the simulation of large-scale atmospheric
558 circulation in high-resolution global NWP models, which is thus important for accurate
559 weather forecasts and/or climate simulations. However, there are still some limitations in
560 this work. For example, this study pays much attention to the medium-range forecast of
561 large-scale circulation in winter of NH. To further validate its effectiveness and robustness,
562 it is necessary to conduct more comprehensive evaluations of the nonhydrostatic OGWD
563 scheme in various numerical models focusing on different weather and climate systems.
564 Additionally, this work only takes into account the effects of NHE on the OGWD. Other
565 factors such as the vertical wind shear could also greatly affect the OGWD (e.g., Xu et al.,
566 2019; Xu et al., 2020; Zhang et al., 2025). While Xu et al. (2021) explored the
567 nonhydrostatic OGWs generated in a constant flow, it remains unclear how the vertical
568 wind shear affects the behavior of nonhydrostatic OGWs which needs further study.

569

570 *Code and data availability.* The China Meteorological Administration Global Forecast
571 System (CMA-GFS) model is archived on Zenodo under
572 https://doi.org/10.5281/zenodo.18476721 (Zhang, 2026). The CMA-GFS outputs and the
573 ERA5 reanalysis data used for the comparison, along with the codes for orographic gravity
574 wave scheme are uploaded to https://doi.org/10.5281/zenodo.18529537 (Zhang, 2026).
